In the other case the tumor occupied the middle and left side of the neck, extending upwards to the level of the upper border of the thyroid cartilage, while below it was lost behind the sternum and the left clavicle. It measured  $4\frac{1}{2}$  inches vertically, and  $6\frac{1}{2}$  inches transversely. On February 26, 1876, three needles were passed into the tumor, and the current was passed through it for nearly two hours. Foveaux's battery was used. Eight cells were used at first, and the number was gradually increased to twenty. After the operation the tumor diminished rapidly in size; on March 23d it measured only  $2\frac{1}{2}$  by 3 inches, and on October 12th,  $1\frac{1}{2}$  by 1 $\frac{1}{2}$  inches. The patient's general health was good, and he felt perfectly comfortable. On October 18th the operation was repeated, Stöhrer's battery, with ten cells, being used. The patient at first did well, but, a fortnight after the operation, inflammation set in and an abscess formed, which was aspirated, and subsequently discharged freely. On December 27th a sudden gush of blood, estimated at two pints, shot from the aneurism, and the patient fell back dead. At the autopsy the aneurism was found to involve the innominate and the transverse arch of the aorta. It was lined anteriorly and above by a dense layer of fibrin an inch in thickness. The true wall of the aneurism was destroyed opposite the first piece of the sternum, and the cavity found at that point contained pus, and communicated with the interior by a tortuous opening. In this case it is fair to conclude that the electrolysis added six or seven months to the patient's life, while it certainly gave him freedom from pain and discomfort.—*Gazette des Hôpitaux*, July 17th, and the *British Medical Journal*, July 14th.

**QUININE EXANTHEM.**—Prof. Köbner, of Breslau, reports the case of a large, powerfully built woman, 28 years of age, who was attacked with a syndrome closely resembling that of scarlet fever, whenever she took even a small dose of quinine. The symptoms consisted in a chill, which was sometimes repeated, a feeling of precordial anxiety, nausea, vomiting, intense headache, high fever, and angina. A few hours after the chill an erythematous eruption made its appearance on the face, and spread rapidly over the entire body. It was attended by intense burning and itching, by slight œdema of the face, and injection of the conjunctiva. The color disappeared for a moment on pressure. The eruption on one occasion completely covered the entire body; on another it was confluent on the upper part of the body, but discrete on the legs. On this occasion the eruption on the legs was slightly papular, and the lower border of the confluent part was not sharp, but gradually faded into the healthy skin. After a variable length of time, according to the amount of quinine taken, the symptoms abated and desquamation began. The angina affected only the posterior wall of the pharynx, the soft palate and pillars being normal. Three times in the course of five months the patient was seized with

these attacks. The first time, the exanthem broke out after  $3\frac{1}{2}$  grs. of quinine had been taken. As a diagnosis of scarlet fever was made, the quinine was continued for eight days, and the eruption persisted for the same length of time. Desquamation then began, and continued for six weeks, and on the soles of the feet, in fact, for nine weeks. The fever was high and persistent, and the prostration was very great.

Three months later the exanthem reappeared, after a dose of  $2\frac{1}{4}$  grs. of quinine. The stage of eruption lasted four days, and the desquamation three weeks. The third time, the exanthem made its appearance after a dose of only  $1\frac{1}{2}$  gr. of quinine. The stage of eruption lasted only two and a half days, and the desquamation fourteen days. The affection this time ran a milder and shorter course than on the two previous occasions.

Dr. Von Heusinger, of Marburg, states that he has met with two cases, in which symptoms entirely analogous to those described above, were produced whenever even very small doses of quinine were administered. In these cases, however, the eruption was confined to the face. Both patients were women. One of them was at one time able to take quinine without inconvenience.—*Berliner klinische Wochenschrift*, May 28th and June 18th.

**ON THE CAUSES OF CALCAREOUS DEGENERATION OF THE ARTERIES.**—Prof. Gubler states that his attention was drawn to this subject by observing the fact, that calcification of the arteries is very frequent in middle-aged and even young men, belonging to the lower orders in Paris, while in the upper classes the affection, as a rule, does not begin to make its appearance until the age of 60. He does not think that the abuse of alcohol has much to do with this difference, but ascribes it mainly to the different food consumed by the two classes of the population. The rich live principally on animal food, and even their favorite vegetables—asparagus, mushrooms, truffles—contain large proportions of nitrogenized principles. The poor, on the contrary, live principally on potatoes, bread, salads, herbaceous vegetables, and fruits, all of which contain large proportions of mineral principles. The blood consequently contains an excessive quantity of salts, which are chiefly earthy phosphates and carbonates, and there is a constant tendency to deposit them in tissues, which are poor in vessels and are nourished by serum supplied by the vessels of neighboring regions. The cure of abscesses and tubercles by calcification is evidence of this tendency of poorly nourished tissues, to accumulate relatively enormous quantities of salts within their organic framework. The middle coat of the arteries, which is poorly supplied with blood-vessels, possesses but little vital activity, and is nourished by the serum which incessantly filters through the internal coat, is especially predisposed to undergo the atheromatous and calcareous degeneration. As evidence of the correctness of this view, Prof. Gubler states that calcification of the arteries is strikingly common among the peasants of the Department of Orleans, which is a calcareous region. On the other hand, in a part of the country which is entirely wanting in chalk, it has been found that the induration of the arteries is only met with in persons of advanced age. In Puy, which is in a granitic and volcanic region, atheroma of the arteries is a rarity. In a convent of Trappists, a religious order which is prohibited the use of meat, the radials were found markedly indurated in half a score of the younger monks, and particularly in the prior, who was only 32 years old. Prof. Gubler does not claim that

he has definitively settled the question of the causation of arterial atheroma, but simply that the above facts supply a step in the right direction.—*Lat Tribune Médicale*, July 15th.

**FOREIGN BODY IN THE MIDDLE EAR WITH UNINJURED MEMBRANA TYMPANI.**—Dr. Schalle reports a case, in which a sudden pain in the right ear was complained of, while the nasal douche was being employed. The patient was deaf on the left side, from the detonation of a cannon-shot, but the drum on the right side was normal, except that there was congestion along the handle of the hammer. The douche was administered by means of a two-ounce rubber syringe. In spite of the use of leeches, purgatives, and low diet, and enforced rest in bed, an acute suppurative inflammation of the middle ear on both sides was developed. Paracentesis of the drum was performed on the right side, and a thin purulent fluid was evacuated. Two days later a black object was seen between the lips of the small wound, and after careful and patient manipulation, Dr. Schalle succeeded in seizing it with forceps and drawing it out. The foreign body was brownish-black in color, irregularly cylindrical in shape, and about one-fourth of an inch in length, by one-eighth of an inch thick. On examination it was found, as had been suspected, to be a piece of hard rubber. After the removal of the foreign body, the inflammation yielded to treatment. Four weeks later the incision had healed, but the drum had not yet regained its normal appearance. A watch was heard on the right side, at about one-tenth of the normal distance.—*Berliner klin. Wochenschrift*, July 30th.

**THE COLD-SOUND (PSYCHROPHOR), A NEW INSTRUMENT FOR TREATING POLLUTIONS, SPERMATORRHOEA, AND CHRONIC GONORRHOEA.**—A little over a year ago Dr. Winternitz, of Vienna, designed an instrument, by means of which he secures the advantages of the mechanical irritation of the urethral mucous membrane by the metallic sound, combined with the anæsthetic and tonic influence of cold. It consists of a double current catheter without eyes, the two canals communicating with one another near the point of the instrument. The instrument is introduced into the urethra until its point has passed the pars prostatica, and it is then attached by rubber tubing to a reservoir containing water at the desired temperature. On turning a stop-cock, the water flows into one canal and out through the other, whence it is conducted away by another piece of tubing. In this way the caput gallinaginis and the entire urethral mucous membrane are exposed to the mechanical action of pressure, and to the sedative action of cold. The success obtained by Dr. Winternitz, by the use of this instrument, was so encouraging from the very beginning, that he has employed it constantly for over a year.

He has treated with it twenty two cases of pollution. Of these two did not return after the first application; one was improved at first, but soon became as bad as before, and the treatment was discontinued after the cold-sound had been used sixty-five times; twelve are still under observation, and have been so much improved by the treatment, that the pollutions occur very rarely, and the secondary symptoms, hypochondria, etc., have entirely disappeared. In three cases the improvement was marked, when the patients withdrew from observation; in two others the pollutions became less frequent, but the secondary symptoms remained unchanged. The two remaining cases are described in detail. In one, the patient was a

Russian officer, forty-six years of age, and the affection was due to excessive venery. The pollutions occurred regularly in the night after coitus, and recurred two or three times a week, when the patient was continent. The cold-sound was used daily for ten minutes with water at 59° F.; during its employment the patient experienced a sensation of pleasant coolness, and the relaxed scrotum contracted energetically. Some difficulty was experienced in removing the instrument. During the four weeks that the treatment was continued, there was only one pollution. The erections became more complete. In the second case the pollutions were frequent, and there were symptoms of excessive spinal irritation. The first introduction of the instrument caused great pain, and brought on an hysterical fit, but these symptoms disappeared after the water (59° F.) had flowed through the sound for five minutes. The treatment was continued daily for three weeks, when the patient was discharged cured. He had not had a single pollution from the time the treatment was begun.

Dr. Winternitz has had sounds made corresponding in size to Nos. 18, 20, 22, and 24. At the first sitting he sometimes uses water at a temperature of 64° or even 66° F., and at a later period sometimes goes as low as 54½° F. Besides the above, he has treated nine cases of spermatorrhœa with the cold-sound. In four of these cases he obtained very favorable results; two cases were very markedly improved, while in the other three the treatment was without special results. In the cases of spermatorrhœa as well as in those of pollution, in which the treatment proved successful, general relaxation of the genitals, and loss of muscular tone in the scrotum were marked symptoms. The cold-sound was also used in five cases of too rapid ejaculation during coitus, and in two cases of obstinate chronic gonorrhœa. In the former its use was followed by at least temporary improvement, and both of the latter, one of which had lasted three years and the other six months, were cured.—*Berliner klinische Wochenschrift*, July 9th.

**TREATMENT OF RANULA.**—Dr. Panas has frequently succeeded in curing ranula by the injection into the tumor of from four to ten drops of a concentrated solution of chloride of zinc. Among others he cites one obstinate case in which excision, seton, and drainage had successively failed; the contents of the cyst were always reproduced, and finally operative interference was abandoned, except when attacks of suffocation rendered palliative puncture necessary. Ten drops of a solution of chloride of zinc, of the strength of one to ten, were injected without previous evacuation of the cyst, and shortly afterwards the injection was repeated with a 20% solution. In less than five weeks from the time this treatment was begun, a complete cure had been produced. This treatment is applicable to all varieties of mucous and serous cysts. It has succeeded in a case of subhyoid cyst, which had resisted cauterization and the injection of tincture of iodine; it yielded to a single injection of chloride of zinc.—*Le Bordeaux Medical*, July 31st.

**NUMERATION OF THE WHITE BLOOD-CORPUSCLES IN DIPHTHERIA.**—MM. Bouchut and Dubrisay have examined the blood of twenty-four children suffering from diphtheria, of whom eleven cases are classed as diphtheritic pharyngitis, and thirteen as croup. Hayem's numerator was employed, and in all ninety-three examinations were made. These examinations demonstrate the occurrence of an increase in the number of white globules, and of a diminution in the number of red globules, in diphtheria. The average number of

white globules was 26,660; in forty-two of the examinations the number was greater than this, and in one it even reached 105,000. The number of globules was only eleven times within the normal limits, viz.: 5,000 to 10,000. The average number of red globules was 4,461,543. The augmentation in the number of white globules was greater in proportion to the severity of the diphtheria. In one case which may be considered as typical, the number varied between 28,237 and 65,887 during the course of the disease; it had reduced to 15,687 on the eve of the patient's discharge, and on the next day fell to 4,706.—*Gazette Médicale de Paris*, July 28th.

**AN EPIDEMIC OF LEAD-POISONING.**—A very large number of cases of lead-poisoning have recently occurred in the 8th and 17th wards of Paris. Dr. Ducamp has had sixty-five of these cases under observation, and he made them the subject of a paper read before the *Société de Médecine Publique*, on July 25th. The patients belonged to all classes of the population; in some families all the members, both old and young, were affected. After careful investigation, Dr. Ducamp found that all his patients were served from the same bakery, and as he could positively exclude all other methods by which the poison could be introduced into the system, he came to the conclusion that the bread was the *agens morbi*. Chemical examination showed that it contained lead; it was evident, however, from the character of the baker, and from the fact that he and all his family were among the most severely affected victims, that the lead was not placed in the bread with criminal motives, while on the other hand, the fact that the water and flour used were the same as were used by the neighboring bakers, whose bread was not poisoned, showed that these substances were not toxic. Dr. Ducamp finally ascertained that the baker had been making use of old wood taken from demolished buildings, to heat his ovens, and here he struck the root of the trouble. This wood had been repeatedly painted with white lead, and when it was consumed by the fire, an oxide of lead was formed, which was deposited in a pulverized form on the floor of the oven. When the embers were withdrawn and the bread put into the oven, the oxide of lead probably adhered to the bottom of the latter, and was removed with it. The correctness of this theory was confirmed by two striking facts: the persons whose duty it was to brush the bread, and who must have detached a portion of the lead and inhaled it in the form of dust, were the first to be affected, and had the most severe attacks. Again, in one family, there were two women, of whom one ate only the soft part of the bread, while the other ate the crusts. The former escaped entirely, but the latter was attacked so severely, that her life was in danger.—*La Tribune Médicale*, August 5th.

**EXTRAORDINARY HYPERTROPHY OF THE MAMMÆ IN A YOUNG GIRL.**—MM. Benoit and Montells report a curious case of hypertrophy of the mammae. The patient, Rosine M., aged 16½ years, was brought before the *Académie de Montpellier* in 1861. When seated, the two breasts were supported on the thighs; when standing erect, the left breast reached five inches and the right breast three inches below the umbilicus. The left breast measured 41½ inches, and the right, 38½ inches in circumference; the pedicle of the former was 27¼ inches, and that of the latter 26½ inches in circumference. The nipples were rudimentary and situated laterally. The hypertrophy had commenced only eighteen months before; all the elements of the glands took part in the enlargement. Subsequently

to 1861, the condition of the breasts remained stationary for many years. In 1862 the patient began to menstruate, but her courses came on irregularly. In 1869 she was married, notwithstanding her deformity, and shortly afterwards her breasts began to diminish in size. Since then she has had three children, and is at the present time far advanced in her fourth pregnancy. One of the children died, but the other two are strong and healthy. Rosine was unable to nurse any of her children, her breasts remaining unproductive, although they became turgid during her pregnancies. At the present time she no longer presents the deformed appearance, that was formerly so marked. When dressed, she has only the appearance of a woman with voluptuously developed breasts. The left breast now measures 13 inches in circumference; the right, 10½ inches; the left pedicle, 13½ inches, and the right, 12½ inches. This case proves the correctness of the views held by Astley Cooper and Velpeau, who believed celibacy to be a cause of hypertrophy of the mammae, and advised marriage in its treatment.—*Le Mouvement Medical*, August 11th.

**VERY RARE FORM OF MONSTROSITY OF THE FEMALE GENITO URINARY ORGANS.**—In the wards of M. Tillaux, at the *Hôpital Lariboisière*, there is at present a small, deformed woman, 26 years of age, who presents an exstrophy of the bladder, with complete absence of the vagina. The external organs of generation are represented only by the orifice of the uterus, which is situated in the median line almost on a level with the skin, and by rudimentary labia minora and majora, which are not united in front. The clitoris, urethra, and anterior wall of the bladder, are absent. The ureters open into the rudimentary bladder near the median line. Palpation shows that the pubic bones are separated in front, by a space that is about as wide as five fingers, and the pelvis seems to be enlarged to that extent. The umbilical cicatrix is located at the middle of the superior border of the exstrophic bladder. The cervix uteri forms a slight prominence, into which the skin is attached. It is conical in form. The cavity of the uterus is of nearly the normal depth, but rectal examination shows that its shape, the organ retains the peculiarities of childhood. The patient began to menstruate at the age of 15 years, and since then has been perfectly regular.—*Gazette des Hôpitaux*, July 21st.

**HYDRASTIS CANADENSIS IN UTERINE HEMORRHAGE, ETC.**—Dr. Gordon, of Hannibal, Mo., states that he has, for the last ten years, made extensive use of the tincture of hydrastis in cases of uterine hemorrhage, with such satisfactory results, that he now seldom resorts to any other remedy. When the hemorrhage is severe, he gives twenty to thirty drops of the tincture at short intervals, until the active bleeding is controlled. The remedy is then continued in doses of from two to five drops at longer intervals. When there is much prostration from loss of blood, he combines the tincture of cinchona flava with the hydrastis.

In menorrhagia, two to five drops of the tincture of hydrastis, every two or three hours or oftener, usually give prompt relief. Larger doses may be used if necessary. After the flow is reduced to its normal quantity, the minimum dose is continued twice a day until the next menstrual period, when, if necessary, the larger doses are resumed. In dysmenorrhœa dependent on chronic endometritis, from seven to ten drops of the tincture, with an equal quantity of a solution of bromine (gtt. i.—Oj.), three times a day, have given very satisfactory results.—*Chic. Med. Jour. and Exam.*, August, 1877.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, September 22, 1877.

## THE PRICE OF REPUTATION.

THE making of a reputation is a speculation in which all engage, but in which few succeed. The latter fact probably explains the perversity of the human disposition to create exceptions to general rules, to make extremes meet, and to accomplish impossibilities. There is a general belief in the eternal fitness of things, which happily reconciles much of our work with failure, and strikes the balance between hope and fruition. It is our duty, nevertheless, to try, if we do not succeed. There is a gratification in the effort, even if our expectations are not reached. The boy who eats merely to get fat has no soul. We have all sorts of maxims to help us up the hill, any one of which are like so many balms in Gilead to heal our wounded hopes. The greatest trouble, however, is not so much in finding workers as in securing those who can appreciate work. The valley of expectancy is strewn with the bones of disappointed geniuses—from the man who thought he earned a crown to the one who died without a hospital appointment. But this is one of the inscrutable rulings of fate, and can no more be explained than the fact that whenever some people sing all the dogs in the neighborhood are sure to howl. If it be agreeable to the dogs, it is far from being so with the singer, unless, perhaps, the latter is willing to believe that his voice has been created merely for the sympathetic responses of his four-footed friends. All we have to say is, that the singer is unfortunate in that association of circumstances which gives him such an audience. This is the best view to take of the matter, and the contemplation of the thought is full of comfort alike to the student who loses the thesis prize, and his preceptor who just misses his election to a permanent membership of the State Society. Hence, we are inclined to pity the communities who might be served more than the individuals who wish to serve them. There is more comfort in such a

thought than any one who has never had occasion to apply it would imagine. We have known of very even-tempered gentlemen who have actually smiled when they have missed an election, and have expressed the satisfaction of being martyrs in their own cause. To do this repeatedly and naturally requires special training.

Like most other good races, this one for distinction is not always for the strong. The weak man who may have good sticking qualities may be the winner in the end. If it be possible to imagine such a thing, he may sing down the very dogs. As a case in point, we know of one gentleman the dream of whose life it was to become an author, and who, after being denied opportunities for half a century, finally, in the absence of a quorum in his local Society, became a delegate to the American Medical Association, and had his paper finally published in the Transactions of that body. As a fitting comment on the completion of his life-work, his obituary appeared in the next volume. He evidently died in the full conviction that it was no easy matter to appear in such a large book, and was doubtless happy and contented. This only proves, among other things, that every one is not appreciated in his own town. For such individuals the people have telescopic eyes and telephonic ears. The farther they are off the better apparently for themselves. Hence, a chance for reputation sometimes centres on a delegateship to some State Society. We have known of instances in which gentlemen who were constipated with modesty at home had a diarrhoea of assurance when away—so much so, that they were making motions at every sitting, and causing their presence to be felt on every occasion. It was considered to be a touch of irony to suggest that a gentleman who became eloquent upon a Chinese emmenagogue he sent to China to further investigate the remarkable properties of the drug; but, after all, it was giving him the extra advantage and charm of distance. This may help to explain why men go from home to be heard.

Then again, if, by hook or crook, a medical man gets a reputation, how many there are who stand ready to criticise his endeavor to advance one science. If a new instrument is invented by Dr. A., Dr. B. is never satisfied until he either puts in a claim of priority for himself or for some antediluvian heathen who in his time could not tell a uterus from a kidney, or diagnose a case of hay fever from sclerosis of the anterior horns. This is in the highest degree discouraging to inventive geniuses. Fair play for the heathen is hardly an argument in favor of such a course, although it is often urged on all such occasions.

But worse than all is a deliberate attempt to belittle greatness when it is known to exist. If Dr. C. is acknowledged as a leader, his friend Dr. B. thinks he is overrated; that he was made by Dr. D.; that he has no education, has vulgar manners, is untruthful, or, perchance, drinks and smokes. From the individuals

the theories are attacked, and there are those who will not even to this day believe that the prepuce is a spinal centre; that the urethra is a receptacle for gun-balls; that carbolic spray is death to all venturesome bacteria; that fractures never shorten; that individual humors can be diagnosticated by the character of the sweat; that pessaries are useful; that the uterus should be incised; that hay fever means congestion of the pituitary body; that mineral waters are good; that mercury is a tonic; and that the plaster-Paris jacket "is an era in surgery." In the face of all these facts, we ask our readers if it is not better to be contented in obscurity?

#### THE VISITING CORPS OF THE HEALTH BOARD.

It will be recollected that some time since the Health Board of this city received an extra appropriation of five thousand dollars for the care of the sick poor. For this purpose forty-seven visiting physicians, at a salary of \$100 per month, were appointed for special duty, from July 18 to Aug. 14, inclusive. We are informed by Dr. E. H. Jones, in his official report to the Board, that: "The services of these gentlemen, forty-seven in number, consisted in visiting from house to house the poor of the city, particularly those residing in crowded tenements, with a view to the relief of children suffering from sickness, especially of a diarrhoeal character. Each visitor was assigned to a district, which he carefully canvassed, visiting each poor family in succession, imparting in every instance such advice as appeared necessary, distributing small tracts containing in the English and German languages plain directions concerning the cure and prevention of diarrhoeal diseases of infancy, and treating such cases of sickness as fell under their observation and were without medical care. In the capacity of sanitary missionaries they visited during the above period, with the aid of five members of the vaccinating corps, 22,566 houses, 131,573 families, treated 4,719 cases of sickness, and distributed 5,128 excursion tickets for the Floating Hospital of St. John's Guild. As these appointments were not all made on the same day, the average number of days occupied in the service was twenty-seven, making an average of about ninety-four visits per day for each visitor."

We are well aware that figures and statistics prove almost anything, but we fail to see the practical utility of any medical visits when ninety-four of them are made in a day. We are glad, however, that these young gentlemen earned, even at that rate, their hundred dollars per month.

**MORTALITY AMONG CHILDREN IN BERLIN.**—The mortality among infants in Berlin diminished in July as rapidly as it increased in June. During the last week in June, 400 more children died than during the last week of July. The diminished mortality was undoubtedly due largely to the setting in of cooler weather.

## Reviews and Notices of Books.

**DER EINFLUSS DER BESCHÄFTIGUNG AUF DIE LEBENS-DAUER DER MENSCHEN nebst Erörterung der Wesentlichsten Todesursachen.** VON DR. A. OLBENDORFF, pract. Arzt in Berlin. Berlin: Norddeutsche Buchdruckerei und Verlagsanstalt. 1877.

THIS is the title of a work the first portion of which has recently been published in Berlin. It is put forth as a contribution to the study of sanitary science, and will appear in irregular parts or volumes, each of which, however, will constitute a complete work in itself. The author has undertaken the difficult but important task of investigating from a statistical standpoint the influence of different occupations on the health and life of mankind. The first number, which is now before us, constitutes the introduction to the entire work, describes the methods of investigation, and discusses the value of the average age at time of death as a standard of mortality in general, and of the mortality among persons engaged in special avocations in particular. The second number, which will appear in the course of the present year, will deal specially with workers in iron.

Although medical literature at present contains many valuable articles on sanitary subjects, the inherent difficulty of the task has hitherto prevented the production of any comprehensive statistical work. The present work, therefore, is destined to fill an important void, and, if carried on in the spirit in which it has been begun, it will doubtless prove of the greatest value to students of sanitary science.

**SOME GENERAL IDEAS CONCERNING MEDICAL REFORM.** By DAVID HUNT, M.D. Boston: A. Williams & Co. New York: Wm. Wood & Co. 1877.

THIS small monograph, which commences with a rapid review of the evolution of medical doctrines in the past, contains some valuable suggestions with regard to the reforms that are necessary in medical education in America. The author claims that an earnest attempt at reform of the methods of teaching, and a thorough adjustment and rearrangement of the subjects taught in our medical schools, would have a far greater influence in improving the character of the graduates than a mere extension of the time of study can have. The result would be less of *clat*, but more of gain.

Dr. Hunt lays bare with an unsparing hand the faults and shortcomings of medical men as a body in America. He denounces the system of favoritism and cliquism in the schools and medical societies. He is particularly hard on the medical lights of the modern Athens, and his remarks must prove rather disagreeable reading to them. The strictures, however, contain so much gall and wormwood that we are disposed to think the author cherishes some personal resentment against the members of the profession in Boston, which renders him incapable of forming an unbiased judgment.

**UNIVERSITY OF BERLIN**—Prof. Helmholtz has been elected to the office of Rector Magnificus in the University of Berlin, for the academic year beginning on October 15th. This election of the celebrated professor of physics to the most honorable position in the University, gives the liveliest satisfaction to all friends of real learning. Prof. du Bois-Reymond has been chosen Dean of the Medical Faculty.

## New Instruments.

### DESCRIPTION OF A NEW DILATOR.

By J. A. STEURER, M.D.,  
OF NEW YORK CITY.

WATER, as adapted to the surgery of strictures, urethral and otherwise, has had a very limited use. Although well known to be a power of the most equal, unvarying, and greatest strength, its use in the dilatation of canals has been confined chiefly to the cervix uteri, as used by Barnes and Molesworth in the form of rubber dilators.

Curling, in his work on "Diseases of the Rectum," mentions instruments for dilatation of strictures of the rectum, in which the pressure was obtained by means of water, but does not go into their mode of construction, nor manner of use. Whitehead and Busch have constructed instruments for the same purpose, also using water.

As far as I have been able to learn, there has been absolutely no use of water as a dilating force for strictures of the urethra, and an instrument for this purpose has never been introduced.

I have also departed from the ordinary agent, rubber (to which are attached certain risks, as will be shown below), as a vessel for holding the water, and have substituted therefor an animal membrane, which possesses many advantages.

In introducing this instrument to the profession I hope, besides calling attention to water as a dilating force in strictures of the urethra, to lay before them a plan of treatment which will be safer, more rational, cheaper, shorter in duration, and for the patient much more pleasant than the ordinary modes of treatment now in vogue.

The instrument is composed of a hollow canula *A*, with a bulb at the end *c*; the portion between *b* and *c* is composed of pure copper, which allows you to make any fixed curve, or a spiral spring, which makes it very flexible. Over *b c* is a membranous tube fastened at both ends. The canula is perforated within

the membrane to allow free passage of water. *B* is a hard rubber syringe, with a graduated piston, and worked with a rack and pinion, the latter being removable. There is also a rubber band attached to the head of the syringe, and passes through the ring of the piston, so that by its own elasticity it draws the latter down, thus making the instrument work automatically, and in proportion as the stricture dilates, the membrane becomes distended. *D* shows the tube distended.

The manner of working the instrument is as follows: the membrane is soaked in carbolized water until it becomes very flexible; all the air is driven out of the tube by compressing the membrane, which is then greased. The syringe being filled with the same water, is screwed on the canula, which is then introduced through the stricture. The water, being forced out of the syringe, gradually distends the membrane, and thereby the stricture.

Although the membrane is very delicate, it is very powerful, owing to the method of its construction, and

the instrument may be used for gradual dilatation or divulsion. There are several points to be considered in the use of this instrument: First. A greater degree of dilatation may be secured at one sitting, and with very much less pain, than with an ordinary sound. The pain caused by introduction of solid instruments through strictures is due to two things: first, distention; and secondly, contraction of the muscles around the unyielding instrument. Now by the use of this instrument, the distention being so gradual, the patient is almost unconscious, and if the muscles do contract, they push the water from side to side without diminishing the calibre. Secondly, you can have any degree of dilatation, from No. 13 to any size French, which obviates the necessity of having a great number of sounds. Another great point is, that you can act upon the diseased surface without irritating the whole urethra by unnecessary contact with instruments, and also allowing you to dilate the parts without cutting the meatus urinarius.

Some might object to the instrument because it has an animal membrane, and might carry infection. This is very easily overcome by using the carbolized water freely.

It may also be used in dilating strictures of the rectum, cervix uteri, and, by substituting a flexible tube for the esophagus. Here let me add that, whilst having great power in hand, it can be easily regulated, and there is no danger of one part suddenly becoming distended, as in the use of rubber instruments, and risking rupture of the parts above.

I have used it with perfect satisfaction in a great number of cases of urethral strictures, and patients who have had sounds passed greatly prefer this method of treatment. The instrument, with extra membranes, is made by G. Tiemann & Co., of this city.

113 WEST 23D STREET.

### PATENT URACHUS WITH CALCULUS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Several months ago I was called to see J. H. B., *act. fifty*, a mechanic of spare habit and always in good health. He complained of soreness and constant pain at the umbilicus, and on examination I found the natural depression filled up by a rounded tumor, apparently the natural tissues enlarged by swelling. There was also circumscribed hardness of the tissues around the umbilicus. The parts were red and very tender to the touch, having every appearance of an ordinary erysipelas.

At the time of my visit he told me that a score or more of years before, after a similar experience, his attending physician at that time removed a "stone" from the umbilicus. I applied a poultice and awaited developments. The above condition continued from day to day, with the exception that the tumor projected more and more from the umbilicus, and the circumscribed hardness decreased. Any movement of the body or handling of the tumor produced severe cutting pain in the part. The tumor was exquisitely tender. No constitutional symptoms accompanied the trouble.

On the tenth day from my first visit I made an incision into the tumor, for the purpose of exploration, about half an inch in depth, when I came upon a hard substance, which, after considerable difficulty, I removed and found to be a concretion, smooth and ovoid in shape, about the size of a medium hickory-nut, and of the color and appearance of a phosphatic calculus,

with a strong, urinous smell. After the removal the wound readily healed. The ordinary retraction of the tissues within the navel fossa took place, and the man has suffered no inconvenience since.

What was the concretion? In the MEDICAL RECORD, No. 354, Dr. Rose's article describing a patent urachus called this case to mind, and I have transcribed the above from my notes of the time.

I cannot conceive this concretion to have been anything else than a calculus, formed from urinary deposit in a patent urachus.

No treatise within my reach mentions anything of the kind, and the novelty of the case is my reason for reporting it.

In this man there was doubtless a similar calculeous formation something more than twenty years before.

LYONS, N. Y., August 29, 1877.

## BACTERIA IN URINE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The RECORD for the 25th inst. contains an article "On the Generation of Bacteria in Urine," by Francis Gerry Fairfield, in which he is represented as saying that the fungous development from dead bacteria is "evidence that some of these low forms of life are animal only in their earlier stages." And further on in the article, after giving the results of his examination of a specimen of urine and potassa which had been standing for some time, he says that "it suggests that monads and bacteria are but stages in a development of life that passes from them into a vegetable form, and finally terminates in the amoeba and the higher animalcules."

Now, a change from the vegetable to the animal kingdom would be evolution extraordinary! and a difficult doctrine to prove. Fungi spring alike from animal and vegetable bodies, and infusions and bacteria, which for a long time have been classed in the vegetable kingdom, are like associated.

The fact also of bacteria being found in the urine six or seven hours after evacuation, as in the case referred to, signifies nothing. Nearly all specimens of urine in warm weather, or almost any infusion of organic matter, will show the same, and often in less time. There are probably few persons who have examined into this question of bacteria but who will quite agree, in the main, with the conclusions of M. du Cazal, as published in France last year and copied in the RECORD for February 10, 1877, as follows:

1. The alkaline transformation of the urine in the bladder may take place when bacteria are not present.

2. Bacteria can live and multiply in urine that continues to have an acid reaction, and which may be even more acid than normal urine.

3. When introduced into a healthy bladder, bacteria are evacuated after a temporary reproduction, without producing any alterations in the urine; on the other hand, when introduced into a bladder that is in a state of chronic suppuration, they become acclimatized and proliferate there almost indefinitely.

4. Finally, they may be present in large numbers in the bladder, and very probably in the kidneys also, for months and perhaps for years, without causing either local or general disturbances.

"It is evident, then, that the very important role which has been attributed to bacteria in the causation of morbid phenomena of the genito-urinary system, does not properly belong to them. The day will probably come when it will be admitted that these elements play but a purely epiphenomenal and absolutely

secondary role, at least in the domain of pathology."

There may be, and probably is, some exceptions to this, perhaps to be found in the *Pathogenic sphaerobacteria* of Cohn, exemplified by the *Micrococcus evincia*, *M. diphthericus*, etc.

Again, the experiments with urine and potassa put into bottles taken from water showing 241° F. heat, cannot be taken as conclusive, since Messrs. Dallinger and Drysdale subjected sporules of flagellate infusoria to a temperature of 300 F. without destroying their vitality.

These gentlemen observed the complete cycle of the *flagella*—from *cereomonads* to the amoeboid condition, their coalition and the formation of a cyst which gave exit to a multitude of granules (sporules) of such extreme minuteness, that, even under a magnifying power of 2,500 diameters, they had not any appreciable dimension. And while examining fluids with a  $\frac{1}{10}$  inch, objective gelatinous points were seen to form where, at first, no sporules could be identified, and their evolution traced until they reach the full monad stage.

What is true of the beginning of the lowest forms of animal life is also true of the vegetable, so far as has been determined, the germs being often so minute that they escaped identification and appreciation. Hence, much of past experimentation is valueless so far as definite results are concerned.

CHAS. E. SLOCUM, M.D.

SHELBYVILLE, Ind., August 29, 1877.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from September 9 to September 15, 1877.*

MURRAY, R., Colonel and Surgeon. To be regarded as temporarily awaiting orders to date from his being relieved from charge of the Medical Purveying Dept. at San Francisco. S. O. 192, A. G. O., Sept. 10, 1877.

MCPARLIN, THOS. A., Major and Surgeon. Relieved from duty in Dept. of the Missouri, and to report in person to the Surgeon-General. S. O. 193, A. G. O., Sept. 12, 1877.

ALLEN, C. H., Major and Surgeon. Relieved from duty in the Dept. of the Columbia, to proceed to New York City, and on arrival report by letter to the Surgeon-General. S. O. 193, C. S., A. G. O.

WATERS, W. E., Capt. and Assistant Surgeon. Relieved from duty at Mauch Chunk, Pa., and to return to his proper station, Fort Columbus, N. Y. H. S. O. 212, Div. of the Atlantic, Sept. 13, 1877.

BENTLEY, E., Capt. and Assistant Surgeon. Relieved from duty at Scranton, Pa., and to return to his station, Little Rock B'Es, Ark. S. O. 209, Div. of the Atlantic, Sept. 11, 1877.

COWDREY, S. G., Capt. and Assistant Surgeon. Relieved from duty at Wilkesbarre, Pa., and to report by letter to Comd'g General Dept. of the Gulf, for orders. S. O. 211, C. S., Div. Atlantic.

MOSELEY, E. B., 1st Lieut. and Ass't Surgeon. Relieved from duty at Scranton, Pa., and to report by letter to Comd'g General Dept. of the Gulf, for orders. S. O. 211, C. S., Div. Atlantic.

CRAMPTON, L. W., 1st Lieut. and Ass't Surgeon. Relieved from duty at Mauch Chunk, Pa., and to report by letter to Comd'g General Dept. of the Gulf, for orders. S. O. 211, C. S., Div. Atlantic.

TAYLOR, M. E., 1st Lieut. and Surgeon. Relieved from duty at Wilkesbarre, Pa., and to report by letter to Comd'g General Dept. of the Gulf, for orders. S. O. 211, C. S., Div. Atlantic.

## Medical Items and News.

**CONTAGIOUS DISEASES.**—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending September 15, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
Sept. 8 .....	1	24	30	3	4	35	0
Sept. 15.....	0	31	29	0	7	04	0

**LEAD IN "AMERICAN LEATHER-CLOTH."**—For some time past a suspicion has been current in Germany, that the so-called "American leather-cloth," which is used as a covering for children's wagons, is injurious in consequence of its containing lead. This suspicion has been confirmed by the occurrence of numerous cases of sickness among children, the symptoms being those of lead-poisoning. An investigation was recently undertaken at the instance of the Imperial Health Office, and in different specimens of the cloth, both of German and foreign make, the enormous quantity of 45.7 per cent. of metallic lead was found; from a piece of the cloth weighing 10 grammes, a mass of lead weighing 4.25 grammes could be obtained. The cloth burned readily, and drops of lead reduced to the metallic form could be seen running off, even when only a small piece of it was ignited. When exposed to direct sunlight, the varnish cracked and began to peel off. The Board of Health, consequently, earnestly warns the public to beware of this wagon-covering, "in the sanatory interest of the children."

**ADULTERATED CINNAMON.**—Three of the most extensive dealers in spices in Mayence, Germany, were recently indicted on the charge of selling adulterated cinnamon. A chemical investigation revealed a not inconsiderable admixture of oxide of iron and crude siderite reduced to a powder. The three dealers were fined 33 marks each, with costs.

**ULSTER Co. (N. Y.) MED. SOCIETY.**—Dr. James R. Leaming, of this city, read by invitation before the Ulster Co. Medical Society a paper on Plastic Exudation.

**PROFESSIONAL HYGIENE.**—The German Government has sent one of the professors of the University of Breslau to England, to study the arrangements made to preserve the health of persons engaged in certain trades and manufactories. The professor has already visited most of the manufacturing towns in England. The diseases studied specially are the necrosis of phosphorus-workers, the cancer of chimney-sweepers, the disease of the bones which affects workers in mother-of-pearl, and the daltonism of railroad employees. The results of these studies will be published, along with an account of the laws at present in force in England, with regard to the hygiene of work-hops and manufactories.

**PUNISHMENT OF A MIDWIFE IN GERMANY.**—A midwife in Breslau, who had previously been fined for insulting a witness and for participation in a theft, was recently condemned to four months' imprisonment for assault and battery. On the ground that her conduct showed a great want of sense of duty and moral control, the Prussian Minister of Public Instruction has

revoked her permission to practise. An unblemished character is considered an essential requisite both for admission as a pupil to the school of midwives and for the obtaining of a permit to practise, and the Minister held that a proper regard for the protection of the people demands that no unworthy person should be allowed to exercise the important functions of a midwife.

**THE AMERICAN DERMATOLOGICAL ASSOCIATION** held its first annual meeting, at the Cataract House, Niagara Falls, N. Y., September 4, 5, and 6, 1877. The following officers for 1878 were elected: President, James C. White, of Boston; Vice-Presidents, C. Heitzmann, L. Duncan Bulkley, of New York; Secretary, R. W. Taylor, of New York; Treasurer, L. E. Atkinson, of Baltimore. The next place of meeting will be Saratoga Springs, on the last Tuesday in August, for three days. After the annual address, by the President, Dr. James C. White, of Boston, the following papers were read: On Molluscum Contagiosum, by Dr. George Henry Fox, of New York; The Etiology of Cutaneous Diseases, by Dr. Lunsford P. Yandell, Jr., of Louisville; On the Eczema Marginatum of Hebra (*Tinea trychophytina cruris*) as observed in America, by Dr. L. Duncan Bulkley, of New York; The Pathology of Seborrhœa, by Dr. Arthur Van Harlingen, of Philadelphia; A Case of True Prurigo (of Hebra), by Dr. Robert Campbell, of New York; On the Immunity of Certain Mothers of Children affected with Hereditary Syphilis, by Dr. James Nevins Hyde, of Chicago; The Lymphatic Theory of Syphilitic Infection, with a New View of the Relation between the Chancre and Chancroid, and Suggestions for the Radical Cure of Syphilis, by Dr. William A. Hardaway, of St. Louis; On the Relation of Impetigo Herpetiformis to Pemphigus, by Dr. C. Heitzmann, of New York; On the Xeroderma of Hebra, by Dr. R. W. Taylor, of New York; On the Treatment of Severe Bed-Sores, by Dyce Duckworth, M.D., Edinb., of London; Case of an Undescribed Form of Fragilitas Cranium, by Dr. Louis A. Duhring, Philadelphia; Two Cases of Very Late Hereditary Syphilis, by Dr. L. Duncan Bulkley, of New York; Acute Conditions of Disease excited by Iodide of Potassium, by Dr. Almon Brooks, of Chicago.

**A DOUBTFUL CASE OF INFANTICIDE.**—A Dr. de Royer was recently called on in France to examine a woman who was accused of having been secretly confined, and of having subsequently destroyed her infant. From the marks on the abdomen and a laceration of the vagina that he discovered, he felt himself justified in concluding that the woman had been delivered of a child of six or seven months. Eight days later a second expert found the same signs, but thought that they might be due to the expulsion of a mole or a fibrous tumor. The case was then referred to M. Polaillon, who agreed with Dr. de Royer, on the ground that a fibrous tumor large enough to produce, during its expulsion, a laceration of the vagina, would certainly have given rise to hemorrhages and have impaired the general health of the woman, while, on the other hand, a mole cannot cause a laceration of the vagina.

**MOUNT SINAI HOSPITAL.**—The place of Admitting Physician to the Mount Sinai Hospital is vacant since Dr. Rudish has resigned. Concerning the position, salary, and other particulars, the latter gentleman (100 E. 58th) may be applied to for information. Application ought to be made to Dr. Jacobi, Secretary pro tem. Med. Staff (still absent from the city).

## Original Lectures.

### LECTURES ON DISEASES OF THE HEART.

By AUSTIN FLINT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE, IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

[Reported for THE MEDICAL RECORD.]

#### LECTURE IV.

##### ANGINA PECTORIS—LESIONS OF THE RIGHT SIDE OF THE HEART—INORGANIC MURMURS.

GENTLEMEN:—I will next direct your attention to a neuralgic affection which occurs especially in connection with lesions at the aortic orifice—namely, angina pectoris.

This affection rarely occurs, with characteristic features, independently of cardiac lesions; but, although commonly referred to the aortic orifice, they are not invariably found in that situation. Angina pectoris is a neuralgic affection, characterized in a typical case by extreme pain, which the patient refers to the precordia as the point of departure, and from that point extending to the left shoulder more frequently, often extending down the left arm, sometimes no farther than the elbow, at other times to the forearm and fingers; in occasional cases extending to the right shoulder and extremity, and in rare cases extending to all the extremities, accompanied with great disturbance of the heart's action in the way of increased frequency and irregularity, and a feeling which is experienced in an intense degree of impending death. These are the features which distinguish a well-marked case of angina pectoris.

It is an important affection, for, when associated with certain lesions, it always involves more or less danger of sudden death; and yet, patients may suffer from this affection for months and years without the occurrence of such a result. I will first say a few words as to the diagnosis of this affection. There is liability to error in this regard, as it is not uncommon for patients of both sexes—more especially, however, the female sex, to experience more or less pain referable to the precordia. These pains generally depend upon intercostal neuralgia, and, to determine that it is not the pain of angina pectoris, but that of intercostal neuralgia, it is only necessary to direct attention to the diagnostic criteria of the latter affection. In the intercostal neuralgia we find the three points of tenderness, or at least two out of the three; we find usually that these patients are anemic; frequently it will be found that they have had intermittent fever, or, more often, that they are affected with pneumonic phthisis. Intercostal neuralgia is a quite frequent concomitant of the latter affection. The pain of intercostal neuralgia is not intense, usually, and it is confined to the precordia or its immediate neighborhood; that is, it does not extend to the shoulder or down the arm, and is not accompanied with that feeling of impending dissolution which characterizes angina pectoris. Moreover, it is not uncommon for patients to complain of a certain amount of pain in the shoulder extending down the arm and producing symptoms somewhat like those of angina pectoris, but it is not sufficiently intense and does not give rise to disturbed action of the heart and a sense of impending death. A physical examination of the heart renders valuable assistance in solving these cases. I refer to this error in diagnosis because I am aware that it has been made, although it would

seem to be a simple matter to make the necessary discrimination between the two conditions.

In addition, there are cases in which the features of angina pectoris are more or less marked without any evidence of disease of the heart. If we were to define angina pectoris as a neuralgic affection associated with disease of the heart, these cases would not belong in the category. Formerly, I regarded this class of cases, those in which the symptoms resembled those of angina pectoris, and yet were not attended by any evidence, either by physical signs or symptomatic phenomena of disease of the heart, as cases of pseudo-angina pectoris. If we do not accept the view that angina pectoris is always associated with cardiac lesion, we must assume that in a great majority of cases disease of the heart, especially aortic lesion, is present. But in a certain number of cases well marked symptoms of angina are present independently of any recognizable cardiac lesion. This is an important consideration in connection with the question of prognosis. If there be coexistent disease of the heart the prognosis differs from that to be given when the angina is not associated with cardiac disease; it is less favorable. I have spoken with regard to the occurrence of sudden death in cases of angina pectoris. What are the circumstances which render this danger greater or less? How are we to appreciate the amount of liability to sudden death? There is no absolute freedom from danger, although we have evidence that the disease of the heart is not in itself at all serious. With regard to that point I have had occasion to somewhat modify the views I formerly entertained. Formerly, when I saw a patient suffering from symptoms of angina pectoris, and these symptoms were associated with physical signs of slight valvular lesion of the heart, I gave the opinion that there was no danger of sudden death. I have, however, been led to modify that opinion somewhat; still, the danger of sudden death, under these circumstances, is comparatively small.

On the other hand, the danger of sudden death in angina pectoris is great in proportion as there is advanced disease of the heart; free aortic regurgitation and dilatation of the heart, with fatty degeneration. Has the patient, then, organic disease of the heart? If so, what, and how important is such organic disease? Has he free regurgitation at the aortic orifice; is there much enlargement with dilatation, and are there any evidences of fatty degeneration? When we are obliged to answer these questions in the affirmative, there is great danger of sudden death in connection with angina pectoris. A patient may, however, pass safely through many paroxysms under these circumstances, before the fatal one is reached. It is not the neuralgic affection itself which destroys life, but it is the associated disturbance of the heart's action that is the important cause of death. I might, in answer to the question—How are we to appreciate the amount of danger?—say that it is in proportion as the heart is disturbed in its action during the paroxysm. If the heart beats regularly, the patient is probably, for the time being, safe. The danger, then, of sudden death in connection with angina pectoris is in proportion as there is feebleness and irregularity in the action of the heart. I suppose the cause of death to be weakening of the heart's action so that the left ventricle becomes overfilled, which of course is most likely to occur with free aortic regurgitation, and the heart is unable to relieve itself by the contraction of the ventricular wall.

If you ask why this neuralgic affection is associated with disturbed action of the heart, which lasts only while the paroxysm lasts, I can only say that proba-

bly in connection with the neuralgic pain there is an influence exerted upon the heart through the *par vagum*, such as prevents the proper regulation of the heart.

We may explain, perhaps, the sudden death which occurs in cases of angina in which there is no disease of the heart present, or in which the disease of the heart itself is not sufficient to explain the death, by supposing that in connection with this neuralgic affection there is an influence transmitted to the organ, similar to the galvanic current, through the *par vagum*, which has the power to arrest its action.

I cannot close the subject without saying that persons may present well-marked symptoms of angina pectoris, without evidence of disease of the heart, and may also recover from the liability to it.

I have met with a few instances of this character.

One case of this kind which I now recall occurred in the person of a physician. He had well-marked paroxysms of angina pectoris, and supposed himself to be in continued danger of sudden death. On examination of his heart I was able to assure him that there was no disease present, and that he was not in the danger he had supposed himself to be.

He resumed his practice gradually, within a short time was pursuing his regular vocation, the paroxysms disappeared, and ten years afterwards was in perfect health, having never suffered from any return of the symptoms. As regards treatment, it resolves itself into measures which may be employed for the immediate arrest of the paroxysm, and those which are indicated by the coexistent disease of the heart; the object being to place the general system in the most favorable condition, so that the paroxysms will be likely to be recovered from, and not prove fatal.

With regard to the paroxysm, the indication is to give more or less freely of stimulants, either alcoholic or ethereal. Of the ethereal preparations, Hoffman's anodyne may be given freely. Alcohol may be administered in the form of spirit and not much diluted, the object being to produce a prompt and distinct impression. In this manner the patient is carried over the paroxysm. A few drops of laudanum, or of the paregoric elixir may perhaps be added to the stimulant with advantage.

We have a remedy which is certainly of great value as possessing the power to arrest the paroxysm very promptly, and that is the nitrite of amyl by inhalation. I have in repeated instances prescribed this remedy, and I know of one patient who had suffered severely from attacks of angina, not passing a day without one and sometimes several, paroxysms, who was able to arrest them so promptly by the inhalation of a few drops of the nitrite of amyl that the affection became quite tolerable.

As regards the second indication, it is essentially that which belongs to the treatment of valvular lesions and enlargement of the heart, and need not be again considered in detail.

#### LESIONS AFFECTING THE RIGHT SIDE OF THE HEART.

We pass now to the consideration of lesions affecting the right side of the heart; lesions involving the tricuspid and the pulmonic orifice. These lesions are rare. When we meet with them they are, in general, congenital; hence it is that we find these lesions in children too young to suffer attacks of articular rheumatism. It is true that acute articular rheumatism occurs occasionally in quite young subjects, but such cases are comparatively rare. I will direct your attention, first, to the tricuspid orifice. It seems that this valve in health is not quite sufficient to prevent

blood from regurgitating; it is a kind of safety-valve, and this leakage has received the designation "safety-valve function" of the tricuspid valve. The mere fact of insufficiency of this valve, then, does not imply an abnormal condition.

At the pulmonic orifice we have lesions similar to those which are to be found at the aortic orifice, though especially involving obstruction rather than regurgitation.

We have corresponding murmurs to represent these lesions. A tricuspid current, however, does not invariably give rise to an appreciable murmur, whereas the mitral regurgitant current almost invariably produces a murmur. This is not easy to explain, but it is a clinical fact. How do we determine that regurgitation occurs at the tricuspid orifice when no appreciable murmur is present? It is determined by the fact that after death the valve permits free regurgitation, as shown by the water-test.

We may determine the fact during life; for, not very infrequently we get a venous pulse on the right side of the neck which is ventricular in character, synchronous with the contraction of the ventricles, and that is conclusive evidence of tricuspid regurgitation, although no murmur is present.

The murmur, when present, of course, occurs with the first sound, like the mitral regurgitant. Indeed, the mitral regurgitant usually coexists with the tricuspid regurgitant murmur. The tricuspid regurgitant is distinguished from the mitral regurgitant by its localization at the right inferior margin of the heart, and its transmission to the right rather than to the left. The coexistence of these two murmurs is determined by the differences in pitch and quality between a systolic murmur at the apex and at the right margin of the heart.

Lesions at the tricuspid orifice lead to dilatation of the right auricle, and, as remote results, to dropsy and cyanosis; the same conditions pertaining as in connection with dilatation of the left side of the heart in consequence of mitral regurgitation.

If there is insufficiency of the sigmoid valves at the pulmonic orifice, we should expect to get a pulmonic regurgitant murmur; and I suppose such a murmur is produced, but it has not been my fortune to meet with an instance in which I was able to recognize it. I imagine that it would be very difficult to separate such a murmur from that accompanying an aortic lesion. If, however, we should find a murmur and could be certain that it represented contraction at the pulmonic orifice, and there was no lesion at the aortic orifice, we might infer that the murmur indicated pulmonic, and not aortic regurgitation.

The pulmonic direct murmur, undoubtedly, exists, and we may determine its presence, and thus localize the lesion without much difficulty. If you place your stethoscope over the second intercostal space, just at the left border of the sternum, the murmur, if present, can be heard. With pulmonic obstructive lesion we have a murmur with the first sound of the heart and having its maximum of intensity at this point, and not upon the right side, as is the rule with the aortic lesion.

But you must not take the maximum point of intensity as the only evidence of a pulmonic direct murmur. It must be associated with the fact that the pulmonic direct murmur is not propagated into the carotid. The aortic direct murmur is almost invariably propagated into the artery.

If, therefore, we find a murmur having its maximum of intensity in the second intercostal space on the left side of the sternum and it is not transmitted into

the carotid artery, the diagnosis of pulmonic direct murmur is made.

There is probably such a murmur as the tricuspid direct, and it is determined by a presystolic murmur and heard upon the right side of the sternum, instead of within a certain space about the apex. Such a murmur probably exists, but I regard it as exceedingly rare.

I do not dwell at much length, as you observe, upon lesions affecting the right side of the heart, and simply for the reason that they are comparatively of rare occurrence and unimportant.

#### INORGANIC MURMURS.

I next propose to ask your attention to inorganic murmurs of the heart—that is, murmurs which are produced without the lesions, which are generally represented by cardiac murmurs. These murmurs, as a general statement, depend upon an abnormal condition of the blood—hence, are known as hæmic murmurs, or, more frequently, as anæmic murmurs, because the condition of the blood which is generally represented by these murmurs is incident to anæmia. Either the anæmic condition itself, the paucity of red corpuscles, disposes the blood to vibration, or some other condition associated with the anæmic state is the cause of the murmur.

At first, perhaps, to those who have not given much attention to this subject, the inquiry arises, if we have an inorganic murmur and are obliged to distinguish between it and an organic murmur, may there not be some doubt in settling the question? This inquiry is natural; but the truth is, we are not usually much embarrassed in determining whether these murmurs are inorganic or whether they are organic.

Let us see, now, of the four important murmurs representing lesions in the left side of the heart, which may be either organic or inorganic. We will begin with the mitral direct murmur, and this leads me to the explanation of a fact which I have not yet mentioned, namely, that we may have a mitral direct murmur without mitral lesion. Perhaps we cannot call this an inorganic murmur, for it is dependent upon lesions, although the lesions are at the aortic orifice and not the mitral. This seems at first hardly probable, but I trust it can be made clear. We may have a loud mitral direct murmur and yet no mitral lesions, and this statement of the fact is based upon physical examination during life, and autopsical examination. I have met with a few cases in which there could be no question with regard to the presence of a mitral direct murmur, and yet, after death no lesion whatever was presented at the mitral orifice. This is the fact, and the question is, how is it to be explained? So far as I am aware, no one has attempted an explanation except myself, and that which I have given is as follows: The murmur occurs in connection with free aortic regurgitation.

What is the condition of the left ventricle as the auricle contracts, when this murmur is present? First in the order of succession of the movements of the different portions of the heart is the contraction of the two auricles. Prior to that, however, the blood is flowing into the ventricular cavity, because of the regurgitation at the aortic orifice; and now, what is the condition of the mitral valve and the left ventricle as the auricle contracts? The ventricle is already partly filled with blood, and the curtains of the valve are floated out so as to come in contact with each other; then comes the auricular contraction and the direct current of blood is forced between those curtains and throws them into vibration, exactly as when the orifice is narrowed, and the murmur is produced.

The murmur, the direct mitral, with free aortic regurgitation, is variable; sometimes it is present, and at other times it is absent, depending upon the variable condition as regards the accumulation of blood in the left ventricle. There is another fact which I have omitted to mention, with reference to the mitral direct murmur when it depends upon lesions at the mitral orifice, and that is, that it may disappear. The disappearance, however, is by no means a good omen. It simply means that the left auricle has become so dilated and the muscular power so diminished that it does not produce a current sufficiently strong, when it contracts, to give rise to a murmur.

I do not think you will find this statement noticed in any work upon diseases of the heart.

In the next place, is it ever questionable whether the mitral regurgitant is an organic or an inorganic murmur? Not exactly; and yet, it is a question whether the murmur indicates important lesion. I suppose that this murmur cannot be called, strictly speaking, an inorganic murmur. We have had occasion to refer to the fact that a murmur at the mitral orifice without regurgitation, is the result of change in the walls of the ventricular cavity, which gives rise to no symptoms and to no danger. It may be produced by a tendinous cord stretching across the cavity, or a roughness of the endocardial membrane. A blowing sound synchronous with ventricular systole, it is said, may be produced by the apex of the heart striking against the little tongue of lung, which is closely adjacent to it, thus pressing the air from the air-vesicles with sufficient force to produce a murmur with inspiration, especially at the end of that act. It is a reasonable suggestion, and will probably account for some instances in which we have mitral systolic murmur without any other evidence of disease of the heart.

Let me caution you about regarding a mitral systolic murmur, when no other evidence of disease of the heart is present, as possessing very great importance. I have a patient under observation who has had a mitral systolic murmur for thirty years, and yet there has never been any trouble connected with the heart.

A mitral systolic murmur is rarely due simply to an abnormal condition of the blood, but an anæmic condition will intensify this murmur the same as it intensifies all the organic murmurs.

Now we come to the aortic orifice, and first with regard to aortic regurgitation, is it ever questionable whether the murmur representing it is organic or inorganic? This question is at once answered in the negative. An aortic regurgitant murmur is always organic; it cannot be produced without insufficiency at the aortic valves.

We have now reached the aortic direct murmur, and it is with reference to this murmur especially that the question will arise as to whether it is an organic or whether it is an inorganic murmur.

When the aortic direct murmur is inorganic, there is often a coexistent murmur at the pulmonic orifice.

What are the circumstances by which we discriminate between an organic and an inorganic aortic direct murmur? We can usually make this discrimination without difficulty, but there are cases in which such discrimination is not easily made. When, however, there is much difficulty in determining the nature of the murmur, it possesses no practical importance.

What are the symptoms which justify the inference that this murmur is inorganic? It may be inferred from other evidences of anæmia, such as pallor of the face and prolabia. Again, we have a physical sign, which is proof positive of an anæmic condition of the patient, and which would lead us to the inference that

the murmur is inorganic, although no other evidence of anemia was present, namely, the venous hum. This is the most reliable physical sign, when present, of anemia, that we possess. To determine whether it is present, turn the head of the patient to the left as far as possible, so that you can place the stethoscope in the triangular space behind the sterno-cleido-mastoid muscle, and just above the clavicle. If then you get a humming sound, it is in all probability the venous hum produced by the current of blood passing through the superficial veins. To render it certain, place the finger on the veins above or below, so as to interrupt the current of blood, and now if the continuous murmur ceases instantly, and is reproduced when the pressure by the finger is removed, the question of the presence of the venous hum is settled.

At the same time we frequently get a murmur in the carotid, particularly upon the left side, resembling the sound of a spinning-top. The French have called it the *bruit de diable*.

The coexistence of this venous hum is a valuable point in determining that the murmur which we get at the base of the heart with the first sound is inorganic or hæmic. The other points are these: If it is a purely inorganic murmur we do not get with it an aortic regurgitant murmur. If we find an aortic regurgitant and an aortic direct murmur associated, the presumption is that the direct murmur is organic. We, moreover, get the pulmonary and aortic second sounds in their normal relation to each other when the aortic direct murmur is inorganic. We do not get evidence of enlargement of the heart if the murmur is nothing more than hæmic.

If there be no evidence of organic disease of the heart beyond the murmur, these points will come in to corroborate the conclusion that the murmur is inorganic; or, if it does depend upon lesion at the aortic orifice, that the lesion of itself is unimportant.

The venous hum is an important physical sign, as indicating the existence of anemia, and important also as indicating to us when the anæmic condition has been removed. It is not uncommon for patients who are suffering from anemia to improve so much as to consider themselves well, and yet the anæmic venous hum be present. It is fair to conclude, if so, that however much the improvement may be, there is room for further improvement, and that continued treatment will lead to a still better condition.

## Original Communications.

### CASES OF PERITYPHLITIC ABSCESS, WITH REMARKS.

CASE I.—By ALMON CLARKE, M.D.,

SHEBOYGAN, WIS.

On the 17th of July last, I saw with my neighbor, Dr. C. B. Cody, a boy thirteen years old, who, seven days previously, had been attacked with a severe pain in the ileo-cæcal region, accompanied by colicky pains in his bowels and vomiting. The day before he had eaten a large quantity of ripe currants.

Opium had been used in doses sufficient to allay the pain; also copious and frequently-repeated injections of warm water, each of which brought away a greater or less quantity of currant seeds, but not much fecal matter.

Four days after the outset of the trouble the boy had a severe chill. Occasional vomiting, constipation,

pain, and tenderness over the whole abdomen, but most marked over lower part of cæcum, completed the history of the case up to the seventh day.

I found the boy with temperature 102° F.; pulse, 84; abdomen rather full, tympanitic, and very tender over its entire surface.

The slightest pressure in front of right hip caused acute suffering. Here, occupying a space of about three by four inches, was a barely perceptible oval elevation, the summit of which was, perhaps, one-fourth of an inch above the general abdominal surface.

By careful palpation this swelling was found to be harder than the surrounding parts, and its outlines tolerably distinct.

Its surface was slightly reddened, but this was probably caused by a simipism which had been placed there two days previously.

There was no œdema of the surrounding parts.

The right thigh was slightly drawn up, but could be extended without marked increase of pain.

Dr. Cody had already expressed his opinion that an abscess existed there. My examination led me to the same conclusion.

The next day, assisted by Drs. Cody and Carl Muth, I operated.

The first step after etherization was to make a puncture in the skin with point of bistoury, over the prominent part of the tumor, about two inches to the left of right anterior superior spinous process of ilium, through which the small trocar of Steurer's aspirator was pushed on into the tumor until it passed the wall and entered a cavity.

Only a few drops of fluid could be drawn out. This was of a greenish, milky cast, scarcely thicker than serum, but of very offensive odor.

Concluding that it afforded evidence of pus, we resolved to go on with the operation.

It was my intention to dissect down by the side of the tube, but it became accidentally withdrawn during a movement of the patient, and as it was not regarded of great consequence as a guide, the operation proceeded without it.

The incision through the integument was one and one fourth inches long, parallel with the axis of the body. The superficial epigastric artery was severed and had to be tied.

The dissection was rapidly made through the abdominal muscles, the length of the external incision being preserved down to the transversalis fascia. Here it was deemed best to explore again with the aspirator, this time a larger tube being employed, which was no sooner inserted than a drop of pus was seen to escape by its side.

The knife was then carried through the wall of the abscess by the side of the canula, making an opening three-eighths of an inch wide, through which the pus poured out in a full stream, and both knife and tube were withdrawn.

The slit in the wall of the abscess was then found with the finger, and the blades of the scissors closed were carried into the abscess, and opened and withdrawn, as was done with the dressing forceps instead of scissors, by Prof. Gurdon Buck, in case reported in *MEDICAL RECORD*, 1876, p. 34.

The wall of the abscess, however, was pretty thick, and this method failed to enlarge the opening to the requisite size, so the ends of the incision were carried on by snipping with the point of the scissors until the opening in the wall of the abscess was as large as the external incision.

The cavity was then explored with the fingers. It

was ovoid in form, the upper part pointing upward and backward. Its capacity was estimated at three ounces. The walls were firm, the lining smooth, and no trace could be found of the appendix vermiformis, unless it formed a part of a narrow ridge which lay upon the upper part of the posterior wall.

The pus was thick, of a brownish green cast, and a decidedly feculent, sulphurous odor.

No currant seeds were found.

A tent of carbolized cotton-wick, and a linseed meal poultice contained in a bag, formed the dressing. The cavity was syringed with carbolized water twice a day for a week, the pus losing its foul odor after two days.

Fifteen days after the operation the wound was healed and the boy was well.

Prof. Erskine Mason says (MEDICAL RECORD, 1876, p. 337): "From cases that have been reported since Dr. Parker first drew attention to the operation, it would seem that the large incision first made was not necessarily indicated, an opening that admits the free escape of pus being all-sufficient."

This means, I infer, that it should be large enough not only to empty the abscess, but also to *drain* it—to guard against too great contraction of the orifice while the cavity is being obliterated.

In my case a cut one and one-fourth inches long proved sufficient. It is probable that a larger abscess would require a larger opening, and I doubt if a smaller opening would answer as well in any case.

#### CASE II.—BY SMITH ELY, M.D.,

NEWBURGH, N. Y.

Mrs. R., aged about sixty-four, mother of ten children, widow. Suffered from occasional attacks of pain in right iliac region since last Christmas, which after rest in recumbent position disappeared in two or three days. Present attack began July 24th, with pain in right side, near the groin, and a small, hard, tender "lump" at seat of pain, but the patient did not take to her bed until the day I saw her, Monday, July 30th.

There was then a tumor in the right ileo-caecal region, exceedingly tender to touch, extending from just within the anterior superior spinal process of ileum downward and inward five inches, by three inches in breadth. Pulse 90, Temperature 102. F. Tumor so sensitive that no satisfactory examination as to existence of fluctuation could be made. Patient had taken physic the day before, which had caused thorough movement of bowels. Ordered tr. opii every four hours, and bland nourishment; warm poultice locally, with directions to send word should any change in symptoms occur during day.

July 31st.—Less pain; other symptoms the same. No vomiting, no sweating, no chill. Said if it were not for pain, she could get up. August 1st, received word early in the morning that patient was worse; found pulse and temperature same, but increase of pain, which had caused a sleepless night, and patient begged that something might be done to relieve her. Believing suppuration imminent, if it had not already taken place, determined to make an exploratory operation to evacuate pus if found, and at least to mitigate pain by relief of tension.

Accordingly, with the kind assistance of my friends, Drs. Montfort, Stone, and Gordon, the patient being etherized, an incision three inches long was made over centre of tumor parallel to Poupart's ligament, and careful dissection made through integument, superficial fascia and muscular layers of abdominal parietes

to transversalis fascia. Exploration by means of aspirator and hypodermic needle in different parts of tumor giving no evidence of pus, wound was plugged with cotton wool, and poultice reapplied. Tr. of opii to be continued.

August 2d.—Patient had passed a comfortable night, pain almost entirely relieved; tenderness of tumor much less; pulse natural; temperature 101 F.

No change occurred until August 5th (four days after operation), when pain was increased. Upon removing cotton from wound, fluctuation was evident, and upon slight pressure a few drops of pus were seen at bottom of wound; puncture with lancet gave issue to a quantity of fetid pus; opening was enlarged upon director. Cavity of abscess explored with finger, afterwards syringed with tepid water. No foreign body was found, bowels moved naturally second day after discharge of abscess.

No further treatment was instituted, and the wound was healed by 20th of August, when, with precaution of compress and bandage, patient was allowed to sit up.

#### LIGATION OF THE EXTERNAL ILIAC ARTERY.

TWO CASES, IN ONE FOLLOWED BY LIGATION OF THE COMMON ILIAC.

REPORTED BY EDWARD T. CASWELL, M.D.,

Surgeon to the Rhode Island Hospital.

THE occurrence, a short time since, of three cases of the above operation, in three different hospitals in New York city, within a few weeks of each other, leads me to report the two following cases. They both occurred in the Rhode Island Hospital in the autumn of 1875, in the service of my colleague, Dr. George W. Carr, by whom the operation was in each case performed. They are the only cases of the kind that have been met with in this hospital since its opening in 1868. The report is condensed from the Hospital Record.

CASE I.—Daniel H., age 36, admitted September 2, 1875. Left popliteal aneurism. Four years before, he had, as he says, a pulsating tumor in the right popliteal space. It was induced by severe efforts in pushing over a tree. One month after the accident the tumor "became perceptible to the touch," began to pulsate, grew rapidly in size, and was attended with great pain and with numbness of the limb. This continued for two weeks, when the pain and numbness subsided, and the tumor became smaller and harder. It finally passed away in about a year, leaving the leg in good condition, but not as large or as strong as before.

In April, 1875, while travelling on foot through heavy snow, he suddenly felt a "weakness" in the left popliteal space, which lasted for five minutes. At that time he detected a small tumor under the left knee, but paid no further attention to it. For two months he experienced, while walking, considerable pain in the knee and leg. It was not until a month before admission that he noticed an increase in the size of the tumor, with marked increase of pulsation, pain, and numbness. On admission the circumference of the left knee and tumor was twenty and one-half inches; that of the other is not recorded.

Here, then, we apparently have the history of one popliteal aneurism undergoing spontaneous cure, and followed by another in the other popliteal space. In the number of the *American Journal of the Medical Sciences* for October, 1875, I reported a case of double

popliteal aneurism, but in that case the tumors originated simultaneously, and not as here, consecutively.

According to the record, the patient suffered intense paroxysmal pain, with considerable and increasing œdema, and with a sensation described as the "filling of the aneurism," which would occur at irregular intervals, and was attended with the most agonizing pain. Compression and flexion were tried without effect. On October 11th the femoral artery was tied in Scarpa's triangle. The patient seemed to do fairly for several days; the pain diminished, and the size of the tumor is said to have diminished, although the measurements are not given. But the œdema of the leg did not diminish, and on the seventh day after the operation there was an offensive discharge from the wound, and about the same time a spot of discoloration appeared upon the heel. On the twentieth day after the operation hemorrhage occurred from the wound. Unfortunately, the record does not state whether the ligature had come away. This hemorrhage was renewed two or three times, and in such amount that on the 1st November Dr. Carr tied the external iliac of the left side, and finding that this did not control the hemorrhage, at once tied the common iliac, which was found to be atheromatous in the vicinity of the ligature. The patient was slow in coming out from the effects of the ether, and complained of much pain in the abdomen. He did not, however, show any signs of improvement, but grew gradually worse, gangrene invading the whole limb, the aneurism undergoing disintegration and discharging offensive pus. On Dec. 5th a copious hemorrhage occurred, the blood coming, according to the record, apparently from the femoral artery. After one or two slight returns of the hemorrhage he was finally released from his sufferings by death on the 10th of December, two months after the first operation.

CASE II.—Thomas C., aged 39, Irish, laborer, married, admitted November 16, 1875. Three months before admission he first noticed a pulsating tumor, midway between the knee and the groin of the right leg. He felt pain in the vicinity of the tumor and in the knee, but kept at work until a week previous to his admission. The tumor was as large as a hen's egg, and on examination a second pulsating tumor, as large as a pigeon's egg was found high up in the course of the vessel. His health had always been good. The circumference of the thigh over the lower tumor was twenty and three-quarter inches. Compression with shot to the extent of five pounds, afterwards increased to seven and one-half pounds, was tried for several days, and borne with considerable persistency by the patient, although producing pain in the knee and in the testicle, just as if the latter had been struck. On November 25th, after consultation, as no progress had been made, the external iliac was tied by Dr. Carr. In a note to me Dr. Carr says, with reference to the aneurism in the groin, that at the operation it was found to extend up along the course of the vessel, "forming a longitudinal dilatation of at least four inches. The part of the artery I first reached in my dissection was thrice its normal diameter, and I was obliged to extend the dissection an inch or more upward to find a proper place for ligation." Hot flannels and sand bags were applied to the limb, and the patient was placed on low diet. The operation was followed by a slight rise of temperature and of the pulse, but everything progressed favorably, the wound in due time discharging healthy pus. On December 12th a little blood flowed from the wound, but it was ascribed to some superficial vessel. The ligature came away of itself on the 15th December, on the twentieth

day after the operation. He continued to do well, sitting up for the first time on January 11th, and on the 31st of that month being allowed to walk about the ward. By the first of March the wound was entirely healed, and on the 8th of that month he was discharged cured. For the past year he has performed hard manual labor without inconvenience.

PROVIDENCE, AUGUST 27, 1877.

## Progress of Medical Science.

FOREIGN BODY IN THE RECTUM.—M. Tillaux reports the case of a man, thirty-six years of age, who, in introducing a bougie into his rectum, allowed the whole of the instrument to slip into the gut. Four days later chloroform was administered, and an attempt made to dilate the anus and rectum. The attempt failed in consequence of induration of the walls of the rectum, due to old scrofulous abscesses in the ischio-rectal fossæ. Only two fingers could with difficulty be introduced into the gut, and all the efforts to extract the bougie were ineffectual. On the following day the patient was made to squat down, and large injections of glycerine and water were administered. After three of these injections had been given, the assistant, M. Quem, succeeded in seizing and extracting the bougie with a pair of forceps analogous to those used in the operation of lithotomy. The patient was seized that evening with severe pains in the abdomen, and died on the next day. At the autopsy an eschar of the intestine was found at the exact point to which the small end of the bougie had reached.—*La France Médicale*, July 28th.

CICATRIZATION OF LARGE WOUNDS UNDER THE SO-CALLED BORDEAUX DRESSING.—Dr. Azam has collated the statistics of a large number of cases of extensive wounds, especially amputations, which were dressed in the manner peculiar to Bordeaux. In this dressing the aim is to secure immediate union of the entire surface of the wound. Its three cardinal points are drainage, deep sutures, and superficial sutures. After the hemorrhage has been controlled as thoroughly as is possible, a thick drainage tube is laid in the deepest part of the wound—in amputations, behind the bone—and fastened over the limb between the two angles of the wound. The flaps are next united at their bases by deeply placed double sutures of very fine silver wire, and the ends of the sutures are twisted over a piece of a sound. These sutures are from two to three in number, according to the thickness of the flaps, and are situated from four to five centimetres from the edges of the flaps. Finally the wound is carefully closed by harelip pins and twisted sutures, supported by strips of charpie dipped in collodion. The entire part is then enveloped in wadding, except at the places where the drainage tubes lie, which are covered with charpie to soak up the discharge. On the second or third day the harelip pins are removed and the deep sutures loosened. The dressing is renewed every three or four days. Cicatrization is completed in from ten to twenty days.

Dr. Azam saw an amputation of the thigh heal up in ten days, and an amputation of the leg in eleven days. In 202 amputations, of which 63 were amputations of the leg or thigh, there were twelve deaths; out of 30 amputations of the thigh there were five deaths, and out of 33 amputations of the leg there were three.—*Wlg. Med. Cent. Zeit.*, Aug. 8th.

# THE MEDICAL RECORD:

## THE SOCIETY SEASON.

The commencement of the society season is always associated with an increased activity in medical affairs. What the colleges are to the students and professors, the societies are to the profession generally. We do not believe that this latter fact is as thoroughly appreciated by society-goers as it should be, otherwise more care would be taken in the selection of subjects for discussion, as well as in the discussions themselves. As a rule there is too much dependence upon accidental circumstances for an interesting and profitable meeting. With the smaller organizations this may be more or less of a necessity, but with the others the case should be entirely different.

So much depends upon the President and Secretary of each society in securing interesting meetings, that at this time we feel like reminding them of their duties. Of the two gentlemen, however, the former is the most important factor of success. Upon the individual exertions of such an officer a society in this city almost quadrupled its membership in an official term, and made a widespread reputation. The reason for this is, that the profession is always willing to second any effort made in the direction of the self-improvement of its members and the free interchange of opinion.

There is such an abundance of valuable material which is suffered to go to waste for the want of a little exertion in securing it, that there is really no excuse why every one of the numerous medical societies in this and other cities should not be filled to overflowing with subjects. There is hardly a society in the land which does not number among its members experts in almost any branch—men who are capable of leading discussions upon any topic of medical interest. Especially is this so in our large cities; and our brethren in the country, shut out from the advantages of hospital experience, pathological laboratories, and the

like, have a right to look to us for a proper utilization of our advantages. That the latter can be done with the least trouble in the society hall is obvious to every one.

The readiest channel for the communication of practical ideas is by means of discussion. In fact, so much interest is taken in the latter that the paper of the evening is oftentimes of secondary importance. Its chief value for a society rests on its suggestive element. Hence, there is no reason why a subject should not be selected merely because it may be old, or that nothing positively new can be said upon it by the author. The very reason why nothing new can be told by one member is an argument in favor of inviting discussion from those who may have had even greater knowledge or more extensive experience.

There are several matters which we should like to see taken up by the different societies, if for no other object than that of reporting progress. Diphtheria, Typhoid Fever, Rheumatism, and Scarlet Fever, are some of the diseases in the treatment of which every practitioner has an abiding interest. We admit that every subject has been handled enough to make it threadbare, but it is evident that discussion must wear them still more before we can unravel many of the hidden mysteries in connection with their respective therapeutical management. We speak advisedly when we say that there is a great demand for practical information upon these and kindred prevalent diseases, and even if there is nothing new to be learned, there is an anxiety to ascertain the fact, if for no other reason than it is satisfying to the consciences of those who wish to be assured that in any given number of cases all the available resources of our art have been known and have been tried. The busy working practitioner is not so much in search of novelties as of practical facts which he can apply in the treatment of his patients, and which will help to establish his reputation as a successful therapist. Let those Presidents of societies who wish to infuse an interest in their meetings take the hint. They can rest assured, if they do so, they can rely upon having large audiences, and an extensive publication of their proceedings.

While upon this point we take the liberty of suggesting that the discussions should be carried on with a certain system, that during each evening two or three leaders should be selected to indicate the different heads of the subject, and bring out the experience of the other members. As a rule, we believe that this system has worked very satisfactorily in this city, and we shall hope to see it carried to still greater perfection the coming winter. Of course we shall hear of the habitual society bore, but even he may be a blessing in disguise by filling up a gap and giving other men a chance to arrange their ideas. Such intermissions between the acts generally relieves a strained attention and freshens our interest in the rising curtain.

## MEDICAL REGISTRATION IN GREAT BRITAIN.

It would appear, from a recent legal interpretation of the letter of the Medical Act, regarding medical registration in Great Britain, that the system is by no means perfect. In a recent case of flagrant quackery, based upon a bogus American diploma, it was impossible to convict the defendant, because it was not distinctly stated in the wording of the Act that any one whose name did not appear on the *Medical Register* was not legally qualified to practice medicine or surgery. The requisite amendment is now strongly urged, upon the plea that the public have a right to be protected from fraud. The object of the Medical Act was principally to create this *Register* of well-qualified practitioners, thereby offering to the public a ready means of discrimination between those who had undergone a regular course of instruction, and those who, without any real ground, passed themselves off as qualified medical men. The Medical Council is the court of arbitration, and has certain discretionary powers, which do not, however, extend to the acceptance of colonial degrees. In the proposed amendment it is suggested that cognizance be taken of such degrees, with a view of showing fair play to all well-educated foreigners who may wish to settle in Great Britain. This is a liberality of opinion in keeping with the spirit of the age, and should be emulated by all civilized countries. Thus far, thanks to the bogus diploma traffic in this and other American cities, the very name of the American medical diploma is associated in the English Courts with the worst of frauds.

## RURAL HYGIENE.

Those of the profession who have been able during the past summer to spend a vacation away from home, have had, as usual, ample opportunities for some practical observations concerning rural hygiene. In proportion as our knowledge of sanitary science increases we the more anxiously inquire concerning the drainage, drinking water, climatic influences, etc., of the different places we visit. If many of our readers can look back upon their experiences of the past few weeks and conclude that all their sanitary anticipations of their respective retreats have been realized, it will certainly be a matter for present congratulation and for future encouragement. We have reason to believe, however, that the contrary conclusion is generally reached; in fact, taking the country as a whole, we must admit that it is in a fearful unsanitary condition. Even in many of the so-called model farm-houses which throw open their doors for summer boarders, we find the foul and reeking privy-vault in close proximity to a well; the rooms small, close, and unventilated, and the dietary stamped with the most objectionable features of boarding-house management. With many of the fashionable first-class hotels, whether on the mountain or beach, the same objections obtain, and but for the out-

door life of the guests, which the season invites, many cases of sickness might have occurred. Fortunately, no cases of hotel sickness have occurred, and this circumstance, considering the protracted droughts, the low level of the water-veins and the baked beds of the countless pools and ponds, is worthy of remark. The religious camping-grounds have been well patronized; and, although much has been done to meet the requirements of a large and crowded population, much more remains to be accomplished before they can be considered safe places to which invalids can be recommended. So far, no cases of serious sickness have been traced to the grounds attributable either to impure drinking water or defective drainage; but this happy condition of things cannot be said to be due to the absence of causes, the active and more direct operation of which is a mere question of time.

## Reports of Societies.

## AMERICAN DERMATOLOGICAL ASSOCIATION.

*First Annual Meeting.*

TUESDAY, SEPTEMBER 4.—FIRST DAY—MORNING SESSION.

[Reported by Dr. L. Duncan Bulkley, Secretary.]

THE American Dermatological Association convened at Niagara Falls, September 4, 1877, and was called to order at 10 A.M. by the President, DR. JAMES C. WHITE, of Boston.

There were present Drs. Atkinson, of Baltimore; Brodie, of Detroit; Bulkley, of New York; Campbell, of New York; Duhring, of Philadelphia; Fox, of New York; Hardaway, of St. Louis; Heitzmann, of New York; Hyde, of Chicago; Taylor, of New York; Van Harlingen, of Philadelphia; White, of Boston; Wigglesworth, of Boston; and Yandell, of Louisville.

The Council presented a report of the work done by the officers in preparing for the present meeting. All the members of the Association had been communicated with in reference to the presentation of papers, and when all the titles had been sent in, their place upon the programme was decided by lot.

The Council had also invited a number of gentlemen who were interested in Dermatology, to be present at the sessions of the Association, and a number of dermatologists in other countries to take part in the exercises by their presence, or by the presentation of papers. Responses were received from Professors Hebra, Sigmund, and Zeissl, of Vienna; Köbner, of Breslau; Profeta, of Palermo, Italy; Engsted, of Copenhagen; Guibout, of Paris; and Anderson, of Glasgow; also from Drs. Güntz, of Dresden, Tilbury Fox, Hilton Fagge, and Dyce Duckworth, of London. A written communication was received from Dr. Duckworth, and printed pamphlets from Drs. Sigmund, Zeissl, Köbner, Güntz and Profeta. A telegram of congratulation was received from Dr. Güntz just before the opening of the session.

The appointment of the Nominating Committee being the next order, Drs. Van Harlingen, Wigglesworth and Hardaway were chosen by ballot.

Drs. Atkinson and Brodie were appointed to audit the Treasurer's accounts.

PRESIDENT'S ADDRESS.

The President then delivered his Annual Address, reviewing the progress of Dermatology in America during the past twenty-five years, and the gradual recognition of the branch in the colleges of the country. The objects of the American Dermatological Association he held to be: First, the formation of acquaintances between those interested and engaged in forwarding the same branch of medicine; Second, by the discussion of subjects and a comparing of opinions, the founding of what may rightly be called an American School of Dermatology; Third, the study of diseases of the skin especially as they appear in America, and for the purpose of securing this properly he suggested the appointment of a Committee on Statistics, for the collection of data; Fourth, the establishment of a nomenclature which will serve as a basis for reporting cases uniformly, for which he would suggest a Standing Committee on Nomenclature; Fifth, to interest the profession and public in the branch of Dermatology.

DR. BULKLEY moved a vote of thanks and the appointment of a committee to report in regard to the suggestions contained therein—carried.

A paper by Dr. Brooks, of Chicago, was then read, on "ACUTE CONDITIONS OF DISEASE EXCITED BY IODIDE OF POTASSIUM." When employed in unusually large quantities within a brief period, he had found these symptoms to follow, in a considerable proportion of cases, namely, fever, arthritis, and iritis. These he considered quite distinct from the same manifestations of syphilis, and thought them gouty in character, this state being excited by the large doses of iodide. The remedy suggested was the employment of tincture of colchicum with calcined magnesia in purgative doses.

DR. TAYLOR had given  $\frac{3}{4}$  iss. of iodide of potassium in the day, reached by increasing doses, without such manifestations.

DR. ATKINSON had seen nasal trouble from gr. x.-xv., three times daily, but had again seen  $\frac{1}{2}$  j. taken three times daily for a month by the same patient, without unpleasant symptoms, after tolerance had once been attained.

DR. TAYLOR believed that if the remedy were increased slowly, much larger doses could be reached; a combination of bromide of potassium with the iodide rendered the use of a less quantity of the latter possible.

DR. DUBRING remarked that no allusion had been made in the paper to the very important and well-known effect which iodide of potassium may have in producing lesions on the skin. He mentioned a case presenting unusual features in a boy of eighteen, who had applied for the treatment of a patch of chronic eczema. There had developed a vesicular eruption, very acute in character, covering the backs of the hands and arms to such a degree that they much resembled a case of confluent small-pox. The vesicles were of a size from that of a large pin-head to that of a large split pea; there was no disposition to rupture; the contents remained clear from five to seven days, then became turbid, and dried up. They occupied the extensor surfaces of the hands and fore-arms more than the flexor, and were very much more marked on the backs of the hands and sides of the fingers than on the palms; there was one large vesicle on the sole of the left foot, and others forming, some on the toes, and a few on the abdomen. The eruption on the hands resembled very much that of scabies, dysidrosis and confluent small-pox; he had never seen dysidrosis

as severe as this, nor as severe as the cases of Dr. Fox; the present eruption had lasted three days. Dr. D. learned that the patient had been taking grs. x. of iodide of potassium three times daily for three or four doses; the drug was stopped, and the eruption began to disappear; after a few days the iodide was given again, and the lesions reappeared; he was then lost sight of.

DR. VAN HARTINGEN, who saw the case, added that the vesicles were umbilicated, like those of small-pox; there was no fever; the pulse was normal.

DR. DUBRING, in response to a question, said that the lesions had a boiled "sago-grain" appearance, as though there were something within them other than serum; when pricked they did not collapse at once, but oozed slowly. He thought the term iodide of potassium eruption inappropriate, inasmuch as it signified very little, because various anatomical lesions can be produced by the drug, even on the same person.

DR. HYDE had given  $\frac{3}{4}$  iss. three times daily for a week, in one case; had never employed so large a dosage in any other case; he had seen some of the effects described by Dr. Brooks produced by small doses of iodide of potassium, in the beginning of its use, though he had never seen any iritis which he could attribute to the drug; he thought that a careful distinction should be made between conditions occurring during the existence of disease and those attributed to the medicine. In regard to the quantity of the iodide of potassium prescribed, he believed that Dr. Brooks occasionally gave as much as 1,000 grains in the day.

DR. TAYLOR had seen arthralgia produced by grs. xv. given three times daily; he recalled the erythematous condition on the face and hands following the use of even small doses, and questioned if the joint difficulty was not produced by a similar erythematous condition of the synovial membranes. He had never seen iritis dependent upon iodide of potassium, but had observed an aching pain through the sclerotic.

DR. HARDAWAY mentioned a case of tubercular meningitis where four or five grains of iodide of potassium, given thrice daily, produced an intense urticaria; the dose was reduced, and even one-half grain caused the reappearance of the urticaria; the eruption had a purpuric tendency, the blood stains remaining several days.

DR. BULKLEY asked Dr. Dubring to give the reasons for excluding the so-called dysidrosis in the diagnosis of the case he had mentioned. The description Dr. D. had given answered so completely to that of Fox and Hutchinson, and to the appearances observed in a very severe case by Dr. A. R. Robinson and himself, that he should have regarded it as one of this disease; this case is fully described by Dr. Robinson, with drawings of the microscopic appearances of sections, in the *Archives of Dermatology* for July, 1877, and need not be here detailed. In this, as in other cases, the eruption ran its course, and reappeared again and again, and Dr. B. asked Dr. Dubring if the occurrence at the time of the administration of the iodide might not be a coincidence, as the case had not been watched in its further development.

The time for adjournment having arrived, the further discussion was deferred until another occasion.

FIRST DAY—AFTERNOON SESSION.

DR. BULKLEY read a paper entitled

"ON THE ECZEMA MARGINATUM OF HEBRA (TINEA TRICHOPHYTINA (URUS), AS OBSERVED IN AMERICA."

In it he gave the details of twelve cases which went

to show that the disease presents much the same features in this country as abroad, but that it is, as a rule, milder in its course. He gave the credit to Bärensprung for having been the first to describe the disease carefully and accurately, under the term herpes inguinalis, five years before Hebra published the first edition of his book, wherein it is called *eczema marginatum*. Dr. B. found a parasitic fungus in all of the cases in which he searched—ten, and all the patients were treated by the free external use of sulphurous acid; he desired to urge the value of this in the vegetable parasitic diseases, and attributed failures in the hands of others to its use in a diluted form, either artificially, or by a natural evaporation of the gas, or, by a change of it back into sulphuric acid, which would prove useless as well as irritating to surfaces thus diseased.

Dr. HEITZMANN remarked that the descriptions corresponded very closely with the disease as seen in Europe. The writer had criticised Hebra's treatment of *eczema marginatum*; he had found Wilkinson's ointment effectual in six days; he would, however, think well of sulphurous acid.

Dr. DÜHRING had seen the disease abroad, both in Hebra's wards and in France and England, but for some years past had seen no cases here until recently; of late he had observed cases resembling somewhat the milder ones described by Dr. Bulkeley; he thought that this disease, as well as many others, occurred in a milder form in Philadelphia than in New York or Boston. He would call it simply *tinea circinata cruris*, and thought that great care should be exercised in distinguishing between ordinary *eczema* and *eczema marginatum*.

Dr. WHITE said that he had observed three different types of the affection under consideration: 1. *Tinea circinata* of the usual type; 2. *Eczema* and *tinea circinata* occurring together, the *eczema* sometimes disguising the *tinea*; these cases were somewhat rare; 3. He had also sometimes met with a disease resembling the *eczema marginatum* described by Hebra, occurring on the thighs, axilla, etc. In these cases he was sometimes unable to assert positively whether *eczema* or *eczema marginatum* were present without the aid of the microscope. Occasionally he was unable to find the parasite even when the various symptoms of *eczema marginatum* were present. Dr. White agreed with Dr. Heitzmann in regarding Wilkinson's ointment a valuable remedy; he was much more apt to resort to it in hospital practice than to sulphurous acid.

Dr. BULKLEY had seen the disease under Hebra, and certainly never saw there any cases as mild as those here detailed. Dr. B. could not quite understand the distinction drawn by Dr. White, but he believed that when the well-defined border made its appearance that was the signal of the presence of the parasite; he held that the therapeutic argument was worth something in this affection, for in cases where the treatment for *eczema* failed, sulphurous acid would often be found to succeed; the latter would irritate instead of cure an *eczema*, as he had himself demonstrated clinically.

Dr. VAN HARLINGEN read upon

#### "THE PATHOLOGY OF SEBORRHOEA,"

and claimed that the scaly affection known as dandruff was not in all instances, properly speaking, a disease of the sebaceous glands, but rather one affecting the outer layers of the epidermis, and should be called *pityriasis simplex* rather than *seborrhœa* or *acne sebacea*, as is commonly the case. The paper was based

on an examination of the scales and débris scraped from the surface, and in the affection named, after extracting the oil by ether, and drying the residue, the loss of weight was comparatively small, and under the microscope the scales represented those of the outer epidermal layer of the skin.

Dr. Fox remarked upon a variety of *pityriasis* of the scalp, in which there was a general exfoliation of the epidermal layer, which, together with some sebum which was present, formed a mass which adhered also to the roots of the hair in the form of sheaths; this under the microscope was composed almost wholly of epithelium. He also referred to a case which had been exhibited at the New York Dermatological Society, where the glans penis was completely enveloped by a membrane of whitish color, which could be separated from it, and which the microscope showed to be composed entirely of epithelial scales; it resembled much the covering sometimes formed by sebum over the glans. He thought the exfoliation of the epidermis in this case was analogous to that occurring on the scalp in *pityriasis*.

Dr. WHITE said that this condition he had once observed in one case to be the beginning of the formation of a horn upon the glans penis. He saw the case two years before the horn appeared; there was first a thickened mass, which could be dug out, like putty, from behind the corona; the horn which grew was large and long.

Dr. VAN HARLINGEN, in answer to a question, said that he would regard *pityriasis simplex* as a separate affection of the scalp, distinct from *seborrhœa*. Modern dermatology seemed to be settling down to but one *pityriasis*, that known as *pityriasis rubra*; he would claim at least one other affection meriting the title, the scaly one of the scalp now under consideration.

Dr. Fox read a paper on

#### "MOLLUSCUM CONTAGIOSUM."

It was based upon twenty-four cases which had fallen under his personal observation. He was not able to trace the contagious element with certainty in any proportion of the cases, but he had noticed what he thought a curious, if not important coincidence, in the occurrence of ordinary warts on many of the patients or their immediate families. He expressed no opinion in regard to the contagiousness of warts, but thought the subject of sufficient interest to warrant further investigation as to the simultaneous appearance of these two skin lesions.

Dr. Fox, in answer to a question, stated that he had seen the peculiar, round, shiny, "molluscous elements" described by Virchow, in the microscopic examination of these tumors of molluscum.

Dr. HEITZMANN had examined two cases microscopically; had found a fatty epithelial degeneration, and the bodies which Virchow had held to be the carriers of the contagion. He believed that there was some propriety in associating warts with molluscum contagiosum; some local irritation took place before the development of both. Discharging tubercles of this disease will have others around them; women with leucorrhœal discharges may have them upon the thighs, and blennorrhœa induces what are known as venereal warts; these latter may occur elsewhere than on the penis as the result of the irritation of this poison; he had seen them on the face in one case. He had also seen a large crop of ordinary warts begin on the hands of a gentleman as the result of laboratory work. Local irritation would not always produce papillomatous growths, but in certain cases there is the predisposition which renders the local agent active.

He did not regard the molluscum contagiosum as contagious in the ordinary acceptance of the term.

Dr. Fox, in answer to a question, said that about one-third of the cases occurred in families where more than one member was attacked; these were mostly children. He thought that in one-half the cases some other member of the family had, or had had, the disease.

Dr. DUNNING could not recall any cases where there seemed to be any connection between this disease and ordinary warts, or even where the latter were present. On questioning, it was found that no one present could.

Dr. HYDE remarked that often, when one would expect venereal warts from the local irritation, none were found, whereas, presently, when we do not look for them, they occur; he thought some vaginal secretions especially productive of them, as they had seemed to cause them after gonorrhœa failed.

Dr. WHITE spoke of the treatment of molluscum contagiosum. He had recently prescribed a means which he had found serviceable in ordinary warts: these latter he orders to be pared down, and then to have them moistened, and pulverized muriate of ammonia to be applied, as much as will adhere. In the case of molluscum, he had had the remedy bored into the masses with a stick moistened and dipped into the same.

Dr. HARDWAY had treated ordinary warts successfully by means of electrolysis: transfixing the base with a needle attached to the negative pole, and placing the positive in the hand of the patient, he passed a current from two or three cells through it for several successive days.

Dr. Fox had not given much treatment to his cases of molluscum; where they were cut off for microscopic examination he had thrust a stick of nitrate of silver into the base. This he considered the best treatment.

Dr. DUNNING had met with molluscum contagiosum several times in private practice; but many present had seen it only among the lower classes of society.

Dr. WIGGLESWORTH had himself had molluscum contagiosum in half a dozen scattered tubercles, which began to appear about two weeks after squeezing the contents from the tubercles on a case of this disease; he was, however, sceptical in regard to the contagiousness of the disease in question.

Dr. ATKINSON had observed it in his own child, there being three small mollusca.

Dr. WHITE had seen several cases in the hospital, in patients who, from their station in life, should have been private patients.

Dr. DUCKWORTH, of London, had sent a paper on "THE TREATMENT OF SEVERE BED-SORES," which was read by the Secretary.

He advised the continuous use of a large poultice, covering the entire surface of the bed-sore; balsam of Peru may be added, if the condition of the sore requires it, or the cataplasma carbonis of the Pharmacopœia may be used. This is the method followed with much success in the St. Bartholomew's Hospital.

Dr. HYDE did not agree with the writer in regard to the value of poultices to bed-sores. He had seen very many of the latter during the late war, and had seen this method tried and abandoned. He mentioned the occasional irritating character of the oil of the flax-seed; he had seen effects resembling hay-asthma following the application of flax-seed poultices.

Dr. WIGGLESWORTH'S paper on "FAULTY INNervation AS A FACTOR IN SKIN DISEASE," was read only by title, it not being yet ready on account of his previous sickness.

The Association adjourned at 6 P.M.

WEDNESDAY, SEPTEMBER 5.—SECOND DAY—MORNING SESSION.

Business meeting at 9 A.M.

The Report of the Treasurer and Auditing Committee was read and accepted.

The Nominating Committee reported the following list of officers for the ensuing year, who were subsequently elected:

For President—Dr. James C. White, of Boston.

For Vice-Presidents—Dr. C. Heitzmann and Dr. L. Duncan Bulkley, of New York.

For Secretary—Dr. R. W. Taylor, of New York.

For Treasurer—Dr. I. E. Atkinson, of Baltimore.

The following gentlemen were elected members of the Association, on the recommendation of the Council; Drs. Wm. H. Geddings, of Aiken, South Carolina; Silas H. Durkee, of Boston; Frank P. Foster, of New York; and S. Sherwell, of Brooklyn.

The following were elected honorary members: Professor Ferdinand von Hebra, of Vienna; Erasmus Wilson, F.R.C.S., of London; and Dr. C. Hardy, of Paris.

The Committee on the President's Address reported the following for adoption:

"The American Dermatological Association agrees in each and every respect with the views laid down in the President's Address, and appoints the following standing committees:

1. *On Statistics*, consisting of: Dr. White, for Boston; Dr. Bulkley, for New York; Dr. Hyde, for Chicago; Dr. Atkinson, for Baltimore; Dr. Van Harlingen, for Philadelphia; Dr. Brodie, for Detroit; Dr. Hardaway, for St. Louis; and Dr. Yandell, for Louisville.

2. *On Nomenclature*: The President, *ex officio*, as Chairman, with Drs. Duhring, Taylor, Wigglesworth, and Heitzmann.

The bibliography of articles written by members of the Association and others, as presented by the President, was recommended to be published with the President's Address, in the proceedings of the Association.

The Council recommended the following changes in the by-laws, which were adopted: Section I. to be altered so as to read: "The annual dues shall be five dollars, to be paid at the beginning of each year. Any member who is in arrears for more than one year shall be dropped from the roll by vote of the Association." Section III. to be amended so as to read: "The titles of all papers to be read at any annual session shall be forwarded to the Secretary not less than two months before the first day of the session, and the titles announced in the notices of the meeting."

The Council also announced, in accordance with Article VIII. of the Constitution (which provides that notice of a proposed amendment shall be given in writing at the annual meeting immediately preceding the one in which it is to be acted upon), that it would, at the next annual meeting, propose to add the following clause to Article IV., namely: "The Association shall have the power to declare forfeiture of membership in the case of any member who ceases to exhibit an active interest in the science of dermatology."

The Association, on the recommendation of the Council, decided that it was not expedient to publish a separate volume of Transactions during the present year; the Proceedings were to appear in the *Archives of Dermatology*, and the Council to return to the authors papers which had been read and accepted, that they may publish them where desired.

Dr. CAMPBELL read a paper on

## A CASE OF TRUE PRURIGO OF HEBRA.

The boy, aged 11, had exhibited the eruption since two years of age, and presented all of the features recognized to be characteristic of the disease.

Dr. DUBRING had seen the case, and was impressed with the correctness of the diagnosis. It was only the second case which he had seen in this country—the other being seen in Boston, a patient of Dr. Wigglesworth, a boy of fourteen. He had, however, seen one in a girl aged twenty, which presented many of the symptoms, and which for a while he thought to be one of true prurigo, but subsequently he had doubted the diagnosis. The girl was in the hospital a number of years, and died while he was absent, and no necropsy was obtained.

Dr. HYDE had seen one case which he considered prurigo.

Dr. FOX saw the patient under consideration, and had no hesitancy in pronouncing it to be one of true prurigo. He had seen one other case of this disease, in a boy five or six years old, which he had exhibited before the New York Dermatological Society. The disease first developed at two years of age, and had remained present since. He had also exhibited another patient before the Society, in whom a chronic eczema so resembled prurigo that the diagnosis between them was difficult.

Dr. WHITE had never seen a case of true prurigo in this country, and believed the disease to be very rare outside of Germany. He had seen a number of cases in which the eruption resembled prurigo very much, but he did not regard them as such. He believed that the diagnosis could not be made on the appearance of the eruption at any one time; the case should be kept under observation, as its character may change.

Dr. WIGGLESWORTH regretted that Dr. White had not seen the case which he had reported in the *American Journal of Syphilography and Dermatology*, January, 1873, and already alluded to by Dr. Dubring. He had seen one other case since that time, which answered in every respect to the disease, except that it did not appear first in infancy; it had begun first when he was from twelve to fifteen years of age, and at the time of observation the man was 40 years old.

Dr. BULKLEY had seen Dr. Campbell's case, and examined it several times, and agreed wholly as to the diagnosis. He had also seen the one exhibited by Dr. Fox at the New York Dermatological Society, and also another case, which Dr. Taylor had observed for a long time, and could describe more perfectly than he, making in all three undoubted cases of prurigo. He had also watched a case for a long time, which he considered at first to be prurigo, but as there was some doubt in his mind he did not wish it to go on record as an authentic case.

Dr. TAYLOR spoke of the case alluded to by Dr. Bulkley. The patient was a Jew, born in Austria, forty years old. The disease had begun in early life, was under observation fifteen to eighteen months, and grew progressively worse during that time.

Dr. HEITZMANN was familiar with the disease abroad, but had not yet seen a case in this country.

Dr. YANDELL had seen one case, which at the time he considered prurigo, but now doubts the diagnosis.

Dr. BULKLEY remarked that the total of the experience of the gentlemen present footed up but six cases of undoubted prurigo in this country; there were three doubtful cases mentioned, and several of the gentlemen had never seen a case in this country.

Dr. HYDE read a paper on

## THE IMMUNITY OF CERTAIN MOTHERS OF CHILDREN AFFECTED WITH HEREDITARY SYPHILIS.

He reviewed the subject of paternal and maternal infection in syphilis, showing that when there was an immunity of certain mothers, it was only apparent; that is, the mother did not fail to manifest the poison because pregnant, but she probably escaped infection—the poison being communicated to the offspring alone by the father. He argued also against the so-called "syphilis by conception," believing that as the blood of the father is contagious, direct infection may take place by means of an abrasion, without the necessity of supposing an infection through the ovum. He believed, moreover, that it was more than probable that Colles's law would be found true in regard to the father as well, namely, that although non-syphilitic, he is never infected from his own syphilitic infant.

Dr. HARDAWAY thought that the law of Colles admitted still further application, namely, that a child born of a syphilitic mother, even though it show no signs of syphilis, was incapable of acquiring the syphilis after birth from the mother.

Dr. TAYLOR believed with Kassowitz that the child may be infected by the father alone, while the mother remains free, as opposed to the view of Cullerier, who denied paternal infection.

Dr. ATKINSON maintained that the syphilitic poison was capable of transmission by any of the elements of the body, blood, sperm, lymph, etc., and was even transmitted by means of the protoplasm, as is evidenced by the infection of the child by the mother through the membranes of the placenta.

Dr. HEITZMANN read a paper entitled

## ON THE RELATION OF IMPETIGO HERPETIFORMIS TO PEMPHIGUS.

It was based on the report of a very interesting case of the former eruption, which afterwards developed characteristic lesions of pemphigus. While not regarding the two affections as identical, he considered them to be closely related, and probably both due to the same cause, yet unknown. Hebra's cases had all occurred in pregnant women, this one of Dr. H.'s during the climacteric period, independent of any disease of the genital organs.

Dr. FOX thought that the elementary lesions were often too much studied in skin diseases, whereas they are only one element in the case. Thus, the term pemphigus is applied to eruptions to which it is inappropriate, simply because of the bullous character of the lesion; the term pemphigus should be restricted to the chronic, fatal form, also to acute forms which are severe and fatal, whereas there are other eruptions presenting bullae, which are similar anatomically, but the disease is of a very different nature. To these he would apply the provisional name hydroa. The cause in the one case is temporary, in the other permanent.

Dr. DUBRING had never seen a case similar to the one of Dr. Heitzmann. He asked if he regarded the disease in the case mentioned as a variety of malignant pemphigus? The lesions of pemphigus varied, there being sometimes pustules rather than bullae.

Dr. HEITZMANN was doubtful as to the true relations of the diseases. He was inclined to retain the name impetigo herpetiformis, as at first there were only small pustules.

Dr. BULKLEY asked in regard to the use of arsenic in this case, and alluded to its very great efficiency in pemphigus.

Dr. HEITZMANN said it had been given in moderate quantity.

DR. BULKLEY said that much in the case reminded him of one of gangrenous pemphigus, which would be reported in the October number of the *American Journal of Medical Sciences*, in which arsenic twice appeared to save life. Early in the disease the case had been mistaken and treated for one of syphilis by those in attendance, there being lesions within the mouth also in this case, which partly led to the confusion. The pulpy condition of the base of the bullæ corresponded much to that described in Dr. H.'s case. He would hardly think that arsenic had received a fair trial in the case reported by Dr. Heitzmann. It is necessary in such cases to increase the dose rapidly, and to take the remedy every few hours, even until some toxic or physiological effects were produced. In the case referred to, the improvement after a few good-sized doses of arsenic was marvellous.

The Association adjourned at 1.30 P.M.

#### SECOND DAY—AFTERNOON SESSION.

DR. HARDAWAY read a paper entitled

##### THE LYMPHATIC THEORY OF SYPHILITIC INFECTION, WITH A NEW VIEW OF THE RELATION BETWEEN THE CHANCRE AND CHANCROID, WITH SUGGESTIONS FOR THE RADICAL CURE OF SYPHILIS.

He entered fully into the literature of experimental and clinical evidence of the absorption of the syphilitic virus through the lymphatic system, demonstrating the same very conclusively. He believed that the chancre and chancroid were both caused by the one virus, their differences being due to a greater virulence in the case of the latter, or to be a pyogenic predisposition in the person infected. Purulence is opposed to infection, and when the virus has been rendered purulent by irritation, there is induced profuse suppuration in the tissues where it is implanted, and as a consequence it (the syphilitic virus) is not generally absorbed even by the lymphatics, and a purulent ulcer or chancroid results: when it is absorbed acute suppuration of the neighboring glands occurs, an eliminative process, and the malady remains local. The proposal for the radical cure of syphilis was the very early excision of the enlarged and indurated glands in the groin, before the poison had passed them and affected the next set of glands within the pelvis. This, of course, could be done only in cases where the case was watched from the beginning.

DR. ATKINSON was much in accord with the writer. The idea that the induration of the chancre was essential to infection was being abandoned, because of the fact that induration is such an uncertain element to determine in every case, therefore the practical results were uncertain. Aside from any peculiar contagion of the chancre or chancroid, all pus is contagious to a certain degree. Now, by repeated inoculation and development, the pus may become so virulent that it is incapable of being absorbed on account of the local irritation which it excites, and the result of the contagion remains local. May not this be the origin of syphilis, namely, a pus which has undergone some change in development, and when this proceeds still further, the more highly poisonous pus is arrested at its point of entry, and results in the chancroid. This arrest is a salutary measure, otherwise the results of the purulent infection might be more destructive of life than syphilis itself. In dissecting wounds, a smaller amount of less virulent poison is absorbed, and infects the system; when the virus is very irritating it is not absorbed, but produces a local sore only.

DR. HYDE thought that conclusive proof existed that syphilitic, as also other infections, took place through

the agency of the lymphatic system. He recalled the experiment of Moser, who laid bare the lymphatic duct in a horse, and injected therein the pus of horse-pox, with the result of having the neighboring glands swollen, and a subsequent development of the constitutional disease.

DR. HEITZMANN criticised some of the experiments and reports quoted in Dr. Hardaway's paper. It is difficult to determine anything definitely from data thus disjointed; some of the observers were reliable, others were not. He believed that ultimately the microscopic study of living matter will determine the true relations of such poisons as syphilis. In healthy persons, the white corpuscles are more coarse and granular than in those with health broken down, as tuberculous patients. Pus corpuscles also present different characters under different circumstances. He believed that there was evidence enough that the white corpuscles convey the poison, and thought the suggestion made of extirpating the infected lymphatic gland a natural one, but he thought it an unreliable method, probably because of the difficulty of determining in advance exactly when it will be successful.

DR. TAYLOR read a paper

##### ON THE XERODERMA OF HEBRA,

in which he detailed the histories of seven cases of this rare affection; five of them existing in two families. The disease began in very early life, and had progressed continuously. Photographs of five of the cases were shown.

DR. HEITZMANN had seen previously four of these cases, and had made the same diagnosis. He had also seen in Vienna the two cases described by Kaposi, and he had had another case under treatment in this country, making eight in all. The case referred to as under treatment is in a man aged forty years, who had had the disease thirty or thirty-one years. There were freckle-like patches on the face and hands, and an ulcerative lesion on the left cheek, which he first called rodent ulcer. He had removed this with the sharp spoon four times. One month ago he removed in the same way four new nodules. They seem to recur about every six months. The wounds heal very kindly after the operation. Microscopic examination of the masses removed shows epithelial cancer, as the masses were called by Kaposi in his case. There was certainly an epithelial new formation, but there were none of the epithelial nests characteristic of this disease.

DR. BULKLEY remarked that three or four of these cases had been exhibited by Dr. Weiss before the New York Dermatological Society several years ago. The name then given to the cases was multiple pigmentary nævi, with lipoid degeneration, which seemed to him to express the clinical features of the disease far better than the term xeroderma, which in this country, as also in several others, indicate quite a different affection.

DR. WHITE called attention to the affinity of this disease to other pigmentary affections, especially to the morphea, as described by Wilson. In this the erythema often persists for a long time, and is then followed by atrophy. The new formations are rather accidental features in the disease, which may take place in other affections as well.

DR. HEITZMANN thought Hebra's designation of xeroderma a correct one, as he considers the atrophic element important.

DR. DURING had never met with anything closely resembling these cases, but he thought the resemblance to morphea, the old keloid of Addison, traceable in some features. In the case of a young lady, an abun-

dant and marked feature of the disease were lesions resembling telangiectatic spots, covering a definite area, lasting for a while and changing into deep pigmentation, which latter again underwent resolution. He thought it difficult to determine certainly if morpha were an hypertrophic or atrophic affection, but inclines towards the latter.

DR. YANDELL read a paper entitled

THE ETIOLOGY OF CUTANEOUS DISEASES.

In it he claimed that aside from parasitic diseases, syphilis, etc., the large majority of acute diseases of the skin, as eczema, urticaria, erythema, etc., were caused by malaria, while the chronic affections were due to scrofula. He instanced the universal prevalence of the malarial poisoning, and that the negro race, who are usually so free from its effects, are likewise remarkably free from the acute eruptions on the skin.

DR. BULKLEY asked Dr. Y. if he had treated cases of eczema by quinine alone, without any other external or internal remedy, and cured them; especially had he treated infantile eczema thus?

DR. YANDELL said that he had.

DR. ATKINSON asked why it was that negroes, who are more prone to scrofula than individuals of any other race, did not have the skin diseases which he attributed to this cause; they should, on his supposition suffer more from them, whereas they are unusually free from all cutaneous maladies.

DR. WHITE asked, if, in the opinion of the writer, these acute skin diseases could occur without a malarial origin?

DR. YANDELL replied, that any agent causing poverty of blood, as alcohol poisoning, starvation, etc., could have the same effect.

DR. WHITE thought that Dr. Y. undoubtedly saw skin diseases in patients with malaria; but intermittent fever is unknown in Boston, and he believes that these eruptions will not be found by statistics to be more abundant in malarious regions than in those where this influence does not exist. He granted that skin diseases could be influenced by malaria, in periodicity, etc., but thought that they could not be thus caused.

DR. BULKLEY was certain that the malarious element was of little or no account in this class of affections in New York City; he would like very much to have the matter referred to the Committee on Statistics for investigation and the collection of data.

DR. HEITZMANN remarked, that the same subject of the influence of malaria in the production of skin diseases had been brought up by Dr. Poor, of Pesth, in Hungary, more than ten years ago, and had been entirely disproved in Hebra's clinic.

Adjourned at 7 P.M.

THURSDAY, SEPTEMBER 6TH.—THIRD DAY.—MORNING SESSION.

It was voted that the council be directed to have the President's Address, together with the bibliography attached, printed with the Proceedings of the Association.

The Association having lost one of its members, Dr. H. C. Hand, of St. Paul, Minnesota, by death, Dr. Fox was appointed a committee to draw up appropriate resolutions. The following was offered and adopted, and ordered to be inscribed on the minutes, and a copy transmitted to the family of the deceased:

"Resolved, That in the death of Dr. H. C. Hand, the American Dermatological Association has lost a member whose character and attainments were such as to command the admiration and win the love of all who knew him."

DR. DURING read a paper entitled

CASE OF AN UNDESCRIBED FORM OF FRAGILITAS CRINIUM.

It had reference to a gentleman, the skin of whose bearded face presented erythematous and scaly patches which appeared to be due to a splitting of the hair within the follicles. The hairs could be extracted without pain, and were largely found to be thus affected. When the beard grew long the splitting caused great annoyance; if, however, he shaved daily, but little trouble was experienced. The hairs were shown beneath the microscope, also drawings of the same.

DR. HARDWAY had had this same patient under observation for some time, but could add very little to what Dr. D. had said. He had seen him lately, and the patient, who is an intelligent physician, thinks he is better. He had contracted syphilis from a wound on the finger, and was now suffering from the constitutional symptoms.

DR. WHITE asked if the splitting begins *within* the follicle, and if the hairs grew to a half-inch in length, would the splitting still be *within* the follicle?

DR. DURING said that at the end of ten days' growth of hair the splitting was very great; it appeared to take place directly at the surface or within the follicle. He regarded the process essentially as an atrophy, although certain portions of the hairs appeared as if hypertrophied.

DR. WHITE could not see how there could be both atrophy and hypertrophy in this case; after the hair is once formed he could not understand how it could increase outside of the follicle. He thought the increase in size only apparent, caused by the separation of the composite parts of the shaft, as in the case of the disease described by Beigel, where the bulging takes place in the shaft, and the masses appear as if hypertrophy had taken place. He had seen cases of this disease; the hair broke off and then the splitting would continue down to the hair; he thought that possibly the splitting might have begun outside the follicle and have continued down into it in the case of Dr. DURING. He suggested epilation as a therapeutic measure in this case, to be repeated and continued for some time, to cause, as it were, the hairs to begin anew. He inquired if the erythematous state of the skin were a primary or a secondary affair?

DR. DURING could not answer this; he had thought that the distention of the hair within the follicle had caused the hyperemia.

DR. BULKLEY read a paper upon

TWO CASES OF VERY LATE HEREDITARY SYPHILIS.

They were presented rather to introduce a discussion of the subject of the very late manifestations of skin lesions in the subjects of inherited syphilis. The cases were in females of twenty-three and twenty-four years respectively, in the former a gummy ulcerating syphiloderma had first appeared within a year; in the other case there had been a recurring or almost continual small tubercular eruption since seven years of age.

DR. TAYLOR had seen several cases of late hereditary syphilis, but is sceptical of skin lesions appearing after twenty years of age; he thought that later lesions would be more apt to be bony, and that the skin enjoys an immunity after the age of twenty years.

DR. ATKINSON referred to his case, published in the Archives of Dermatology for January, 1877, of syphilis inherited through two generations. In this instance the eruption had reappeared since the case was published; that is, at about the twentieth year.

DR. BULKLEY said that there could be no question in regard to the syphilitic character of the eruption in

the cases reported; in the first case, a large share of the indications of hereditary syphilis were present, the teeth were most typically notched and deformed, the history of the mother in regard to syphilitic eruptions, abortions, etc., were perfect. The girl had certainly not acquired the disease, and the gummy masses were yielding rapidly to antisiphilitic treatment. He differed entirely from Dr. Taylor in regard to the immunity of the skin late in hereditary syphilis; these cases were rare, but others had been observed as well.

DR. WHITE, speaking in regard to the value of the notched teeth, said that he knew of a case of a boy who presented the central incisors notched from side to side, and the lateral incisors wanting, where the suspicion of syphilis was excluded with the most absolute certainty; all the other teeth were normal. The deformity followed a sudden and severe attack of inflammation of the glands of the neck.

DR. BULKLEY recognized and had been accustomed to point out deformities of the teeth which often resembled those recurring in hereditary syphilis, and he believed that the practised eye could determine with very great certainty those due to the action of the syphilitic poison and those dependent upon scrofula, acute sickness, etc.

DR. VAN HARTINGEN exhibited some leaden tubes, such as are used to hold liquid paints, which he had employed to contain ointments; he had gotten the suggestion from some French source. They are particularly serviceable when travelling, or when ointments were to be kept a long time; he had found diachylon ointment to harden from exposure to the air when dispensed in the ordinary manner.

DR. BULKLEY suggested that he had found that a layer of water placed over the surface of diachylon ointment preserves it perfectly.

DR. WHITE at first had difficulty with this ointment, but now he has no trouble in keeping it at any time; it is always soft and of the consistency of butter. He is careful to always have only the best olive oil used, and a small portion of oil of lavender is added.

DR. HERTZMANN said that there was no difficulty in Vienna with the diachylon ointment; the main point to be observed in making it is always to boil it over a water-bath. When there is no counterindication he adds balsam of Peru (3 i. ad  $\frac{5}{2}$  i.); it keeps better, and the fragrance is pleasant.

DR. DÜHRING adds a few grains of benzoin to the ounce.

DR. ROBINSON'S paper on

#### THE PATHOLOGICAL HISTOLOGY OF PSORIASIS

was read only by title, owing to the absence of the writer.

DR. WIGGLESWORTH'S paper on the

#### AUTO INOCULATION OF VEGETABLE PARASITES, AND THEIR NON-IDENTITY,

was read only by title, as also that of DR. TAYLOR, on

#### AFFECTIONS OF THE TESTICLES IN HEREDITARY SYPHILIS.

It was moved and carried, that the Association direct to be printed at the beginning of its Proceedings the following:

"In accepting papers read before it, the American Dermatological Association by no means indorses all or any of the opinions expressed in them."

A vote of thanks to the proprietors of the "Cataract House" for courtesies extended to the Association, was unanimously passed.

The Association adjourned to meet next at Saratoga Springs, on the last Tuesday in August, 1878.

## Correspondence.

### GUTTA PERCHA TISSUE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The drug shops now contain a preparation of gutta percha which will be found very convenient for some surgical uses.

It is rolled out in sheets about one yard wide, and as thick, or rather as thin, as fine French writing paper.

Both surfaces are perfectly smooth, of a satiny lustre, and the sheet is translucent almost to transparency. It is very cheap, much more so than oiled-silk, for which it is to some extent convertible, and to which it is for some purposes superior.

It is of course perfectly pliable, and slightly ductile and elastic.

It is unaffected by the heat of the body, but softens at a heat somewhat higher. It is insoluble in water but soluble in ether, chloroform, and alcohol, and it is of course impervious to any fluid which does not dissolve it.

The uses for which I would commend it are as a substitute for plasters of all kinds employed in wounds or lesions of the hands.

For example: a cut upon the finger may be treated by winding smoothly a narrow ribbon of this tissue around it. Two or more thicknesses may be made. A lighted match passed a little way above the surface will seal by fusion a band of this dressing and leave a neat, light, clean, impervious cover to the wound, which will permit the hands to be placed in water. Adhesion of cut surfaces and resolution of infiltrated deposits take place very quickly and kindly.

If a broad patch of the skin is to be shielded from the air, as for example a scalded surface or a patch of eczema, a piece of the tissue somewhat larger is laid upon it and sealed in position by tracing the margin with a camel's hair pencil dipped in chloroform, precisely as we adjust a covering glass to microscope slide. Lesions thus "mounted" remain under observation, covered, but not completely hidden.

The method is to be especially commended for the antiseptic dressing of incisions.

Some experience in these several uses leads me to commend them to the general notice of the profession.

W. M. CHAMBERLAIN, M.D.

68 WEST 40TH STREET, Sept. 17, 1877.

### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from Sept. 16, to Sept. 22, 1877.*

HAPPERSSETT, J. C. G., Major and Surgeon. Relieved from duty at Wilkesbarre, Pa., and to return temporarily to his proper station, Fort Hamilton, N. Y. H. S. O. 216, Div. of the Atlantic, Sept. 18, 1877.

DE GRAW, C. S., Capt. and Asst. Surgeon. Relieved from duty at Carlisle Barracks, Pa., and to return to his proper station, Oglethorpe Barracks, Savannah, Ga., and there await further orders. S. O. 216, C. S., Div. of the Atlantic.

KIMEALL, J. P., Capt. and Asst. Surgeon. Assigned to duty at Wilkesbarre, Pa., relieving Surgeon Happerssett. S. O. 216, C. S., Div. of the Atlantic.

EWEN, C., Capt. and Asst. Surgeon. Relieved from duty at Easton, Pa., and assigned to duty with U. S.

Troops at Scranton, Pa. S. O. 216, C. S., Div. of the Atlantic.

DICKSON, J. M., Capt. and Asst. Surgeon. To proceed to Jackson Barracks, La., close his money and property accounts at that station, and then return with least delay practicable, to his post at Indianapolis, Ind. S. O. 216, C. S., Div. of the Atlantic.

SKINNER, J. O., 1st Lieut. and Asst. Surgeon. Relieved from duty at Reading, Pa., and assigned to temporary duty at Carlisle Barracks, Pa. S. O. 216, C. S., Div. of the Atlantic.

## Medical Items and News.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending September 22, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Mosles.	Diphtheria.	Small-pox.
Sept. 15.....	0	31	31	3	7	40	0
Sept. 22.....	0	27	38	2	6	45	0

YELLOW FEVER.—This disease has prevailed for some considerable length of time at Havana, has made its appearance at Fernandina, Fla., and finally has been brought to Quarantine at New York. The Havana authorities have refused to issue clear bills of health to vessels leaving that port while this fever was there, but the quarantine officials at Fernandina, it seems, have not hesitated in giving clear bills of health to vessels which have touched at that port, notwithstanding the disease at the time was prevailing in that place. Rigid quarantine, however, has been established against Fernandina, and doubtless an illegitimate spread of the disease will cease.

At Gainesville, Fla., are several boxes of goods received from New York, but, because they were delayed at the port of Fernandina some four or five days, their removal from the storehouses has not been permitted. In Havana, the fever is more prevalent and fatal than during the months of July and August; also at Fernandina, it is still spreading, and an increasing mortality is expected. The rigid and prompt quarantine at the port of New York has prevented the disease from finding its way into the city, except, perhaps, in one or two instances, and it is to be hoped that the number of cases in this latitude will be limited to the half-dozen now on board the hospital ship Illinois, in the lower bay.

DR. JOHN A. WYETH.—This gentleman has resigned his connection with the Bellevue Hospital Medical College.

PARENCHYMATOUS INJECTION OF ERGOTINE.—Dr. L. Collins, of Guilford, Ind., in *The Clinic*, speaks favorably of injecting a solution of ergotine into the tissue of the cervix in cases of subinvolution of the uterus and chronic engorgement of the neck of the organ. He uses a needle about four and a half inches long, attached to a hypodermic syringe; operates through a common glass speculum, first producing local anaesthesia by placing a pledget of cotton, saturated with chloroform, against the os, and throws into the cervical tissue a solution containing two or two and a half grains of Squibb's ergotine. The injections were re-

peated every six days. Very little local irritation is said to follow, and the pain, if any exists, soon assumes an intermittent character.

PLASTER-OF-PARIS JACKET.—Dr. J. Bryan, in the *Louisville Medical News*, for September 15, 1877, defends his claim to priority in the use of the plaster-of-Paris jacket in the treatment of Pott's disease. He claims to have applied it first in the summer of 1874, in Bellevue Hospital.

LECTURER ON ANATOMY.—Dr. Joseph D. Bryant has been appointed to lecture on Descriptive and Surgical Anatomy in Bellevue Hospital Medical College, in place of the late Prof. A. B. Crosby.

OPIMUM-SMOKING, AND A GOVERNMENT EDICT.—The Chinese Government has taken the initiatory steps for suppressing the vice of opium-smoking, by passing a permissive edict, calling upon the governors of the various provinces to suppress indulgence in the habit. With what success the edict will be crowned remains to be seen, for three years are to elapse before it goes into force.

MEDICAL COLLEGES.—The preliminary courses of lectures have commenced in the Bellevue Hospital and University Medical Colleges of this city. Both schools have opened with an unusually large attendance of students.

SMALL-POX has disappeared from Dublin, there having been but one death in that city during the past seven weeks.

CRIMINAL DISSECTION.—The House Surgeon of the Glasgow Maternity Hospital was arrested for violating the Anatomy Act, in dissecting the dead body of an infant against the expressed wish of its mother.

EDINBURGH.—The annual death-rate of Edinburgh, Scotland, is about fifteen per thousand.

WAR AMBULANCES AND THE TURKISH SICK.—A correspondent of the *Times* writes: "On this third day of August there is an army of thirty-five thousand men without a litter, without one single ambulance wagon, without one case of surgical instruments, and neither here (Constantinople), nor at Kars, nor at Erzeroum, has a shilling of the money so nobly subscribed by the English public been received."

PROVIDENT DISPENSARIES.—Efforts are being made to consolidate the various provident dispensaries in London under the government of a central board. The object of this is that members of different dispensaries removing from one district to another, shall be able to avail themselves of all the advantages afforded by the provident dispensaries of their new district without fine or entrance fee. It is proposed that the Central Board shall be composed of members from each district.

EDUCATED MIDWIVES.—A correspondent deplors the want of educated midwives who might be in attendance upon patients during the uncertain dilating period, and thus save the medical attendant proper the sacrifice of much valuable time. We have some hopes that the Training School for Nurses may in time overcome the difficulty.

BRITISH MEDICAL ASSOCIATION.—The meeting of the British Medical Association at Manchester, England, is spoken of by the English press in faint praise as a social and scientific success. Judging from the published reports the latter seems pre-eminently to have been the case. Several American gentlemen were present, among whom were Drs. Sims, Sayre, and Barker, of this city, and Prof. H. D. Didama, of Syracuse. All were cordially welcomed and hospitably treated.

## Original Lectures.

## LECTURES ON DISEASES OF THE HEART.

By AUSTIN FLANT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE, IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

[Reported for THE MEDICAL RECORD.]

## LECTURE V.

## FATTY DEGENERATION OF THE HEART—ENDOCARDITIS—PERICARDITIS.

GENTLEMEN:—The next topic which I propose to consider is fatty degeneration of the heart. The pathological change in a heart which has undergone fatty degeneration exists in the muscular substance of the organ, and consists in the substitution of fatty granules or oil-drops for the muscular elements.

It is an important condition, and involves some difficulty in diagnosis. It is important with reference to measures of treatment, with the view of preventing further fatty change, and, if possible, to secure the patient against certain accidents which are liable to occur in connection with this condition, sudden death being one, and rupture of the heart being another. As regards symptoms and danger, the important point is this: in proportion as the fatty change takes place, the power of the heart's action is impaired. The heart is weakened in proportion as it undergoes fatty degeneration. This is the criterion; and that it is which underlies the physical evidence of this disease. We may have fatty degeneration of the heart in conjunction with valvular lesion, and this fact renders the diagnosis almost impossible, if there be enlargement of the heart present. It is only probable, and that simply because the evidence of weakness of the heart is out of proportion to the amount of enlargement. Yet, with valvular lesion present, we may reach a diagnosis with a certain degree of positiveness. The physical signs of this affection are such as represent persistent weakness of the heart's action. The absence of much or any enlargement of the heart enables us to exclude dilatation as the cause of the weakness. Now, what are the physical signs of this condition? First, there is a feeble impulse, but I do not attach any great amount of importance to this, especially if there is a considerable layer of adipose tissue over the chest. In a thin subject, however, we may derive some information from palpation.

The most important physical sign relates to the first sound of the heart, as heard over the apex. In proportion as the muscular tissue of the heart is weakened by fatty degeneration, as when weakened by dilatation, the first sound becomes weakened, and it may become extinct. We may hear only the second sound of the heart, on account of the extinction of the first sound over the apex; and when the first sound is heard, it will be found that it has changed in character. It will be short and clicking, valvular in character—the same changes as those which belong to dilatation. When, therefore, we find this physical condition persistent, and in connection with certain symptoms, we have the evidence of fatty degeneration of the heart. What are the symptoms which are to assist us in making the diagnosis? In the first place, the age of the patient is an important consideration. Fatty degeneration of the heart does not occur under forty years of age; it is hardly admissible under that

period in life. The general condition of the patient as regards obesity, has some value as evidence, but is not of much weight. We more frequently find fatty degeneration of the heart in persons who show obesity, although it is found in those who are thin.

We direct attention to the eye, as a certain diagnostic value pertains to fatty degeneration of the cornea—the *arcus senilis*, as it is called. When attention was first called to this change, and the character of the change was ascertained, it was thought that we had a reliable criterion to fatty degeneration of the heart; that when the one existed the other was present, as a matter of course. Clinical facts, however, have shown that it does not follow that the presence of one establishes the existence of the other. The co-existence of the *arcus senilis* with other signs and symptoms possesses a certain amount of weight, and its absence also may have a certain value by way of exclusion.

Accompanying the feebleness of the central organ of circulation, we also have want of breath upon slight exertion, and tendency to syncope; perhaps falling into a condition of syncope frequently.

Then there are certain seizures, described first by Dr. Stokes as pseudo-apoplectic seizures, which are said to have a connection with fatty degeneration of the heart. They are a kind of semi-unconscious conditions, in which the patient may remain, perhaps, for hours. Dr. Stokes has pointed out a very interesting disturbance of the rhythm of respiration in these cases. This peculiar aberration in breathing was also described by Dr. Cheyne, and it has received the name of the Stokes Cheyne respiration.

The characters are these: The patient, when sleeping, breathes with a diminution in the intensity and an increase in the interval between inspirations until at length inspiration is very short, and a long time elapses before another follows; so long is this interval sometimes, that it seems as though the patient had breathed his last. Finally, the patient is roused suddenly, opens the eyes, breathes with a little more intensity and diminution in the length of the interval between respirations, improvement progressively takes place, and after the lapse of a few minutes respiration and consciousness are fully restored. This is not a very common form of aberration, but it is very striking, and the intervals between respiration are sometimes so long, and the appearance of the face is such, that the patient is as one dead.

Dr. Stokes regarded this kind of respiration as pathognomonic of fatty degeneration of the heart, but further clinical observation has shown that it has no pathognomonic character, and that it may occur without cardiac disease.

As regards treatment the patient's general health should be placed in the best possible condition. Give the patient good blood; prescribe digitalis as a cardiac tonic. It is sometimes customary to prescribe digitalis, as a matter of course, whenever cardiac disease is present, but a certain amount of discretion is to be used in the use of this drug. A powerfully acting heart does not claim the effect of digitalis. The drug under these circumstances does harm; it augments the action of the heart beyond what is useful. The indications for digitalis are weakness, rapidity, and irregularity of the heart's action. In the treatment of this affection it is to be borne in mind that there is a certain amount of liability to sudden death. Fatty heart in that regard holds the same place among lesions affecting the walls of the heart, that the aortic regurgitation holds among valvular lesions. Sudden death takes place from rupture of the heart, incident to fatty

degeneration. The most common condition which occasions rupture of the heart is weakness of the walls due to fatty degeneration. When sudden death does not take place as the result of rupture, the mechanism of death I suppose to be the same as when we have aortic regurgitation with dilatation of the left ventricle. The weakness of the ventricular walls, under circumstances in which the cavity becomes overfilled, prevents the organ from having sufficient power of contraction to relieve the cavity of the blood constantly accumulating, and the heart becomes paralyzed. The first object, then, in treatment is to give the patient, as far as possible, good blood. This is done by proper dietetic regulations, by the use of chalybeate tonics, if required, and the adoption of proper hygienic measures.

If at any time unusual weakness of the heart manifests itself, a certain amount of benefit, as already stated, may be derived from the judicious use of digitalis. Strychnine and nux vomica also exercise a tonic effect upon the heart. The patient should be cautioned against over-exertion, over-excitement, or anything which causes an unusual accumulation of blood in the heart. The restriction of the patient's exercise must be made with discretion; for, if he has been leading an active life, a general debility may be induced by a deficient amount of exercise. He should, as a rule, take such exercise as he can take without discomfort; it is allowable and desirable. These are the objects to be kept in view in the treatment of fatty degeneration of the heart. It has been supposed that in view of the fact that the lesion consists in the deposit of fat, the diet of the patient should contain only a very small proportion of fat; that fatty articles of food should be excluded. It is not clear that this has much influence on the lesion; still the quantity of fatty articles may, perhaps with propriety, be restricted within certain limits.

#### ENDOCARDITIS.

I will next make a very brief reference to endocarditis. The inflammatory affections of the heart are endocarditis and pericarditis. Carditis possesses but little practical importance; except as associated with pericarditis and endocarditis, it is so exceedingly rare that we may almost ignore it. The recognition of endocarditis as a distinct disease belongs to modern times. Its discoverer, BOULLAUD, still lives.

At the present time we know that it is a pretty common affection, and we know this chiefly in its connection with rheumatic pericarditis. It occurs otherwise, as, for example, in connection with Bright's disease and the acute infectious disorders. It probably occurs in connection with causes with which we are not at present fully acquainted. Its presence cannot be ascertained during life except by means of physical signs. It gives rise to no rational symptoms which are diagnostic. It never occurs as an acute affection. It is never ushered in with acute symptoms, as most other diseases are.

There is a form of endocarditis which leads to ulceration, and hence is called ulcerative endocarditis, and it is supposed, and with good reason, that, from the ulcerated surface, there gets into the blood sanious matter which produces septicaemia.

We do not, however, have endocarditis producing a febrile movement, such as would lead us to suspect the presence of an acute affection. It is the local sign alone which points to endocarditis. We base the diagnosis upon the result of physical exploration.

Now, very briefly, let me endeavor to impress upon your minds the method of making the diagnosis. I

will do that in connection with the history of the case before us. This man entered the hospital while suffering from acute tubal nephritis. While in the hospital he had endocarditis. What was the evidence? It was this: this patient was examined when admitted, and repeatedly after entering the hospital, and no cardiac murmur was found. He was examined sufficiently often and with sufficient care to warrant this negative statement. But, after having been in the hospital for a certain length of time, a cardiac murmur was heard, and he has that murmur yet remaining. What was the murmur? He had a mitral murmur; that is to say, he had a murmur referable to the mitral orifice. It was a systolic murmur. It was a murmur which did not give evidence of mitral regurgitation. It was rather loud and rough, but was not transmitted laterally about the chest. Its maximum of intensity was at or near the apex of the heart. It was a mitral systolic non-regurgitant murmur developed while the patient was under observation, and suffering from acute Bright's disease. Now, we have the basis for a diagnosis, and it is the development of this murmur while the patient was under observation.

Suppose that the patient came into the hospital having a cardiac murmur, it would simply be evidence that at some previous date he had had endocarditis. To complete the proof of the development of endocarditis the murmur must be developed while the patient is under observation.

According to this man's history, the murmur which is diagnostic of endocarditis appeared on the sixth day after his admission to the hospital, and was noted in the history-book as follows: May 10th (no murmur having been heard previously). "There is heard a soft blowing murmur at the apex with the first sound of the heart, and not conveyed to the left. A similar murmur is heard at the base, and is transmitted into the carotid. Over the body of the heart is heard a harsh, loud systolic murmur." We had the first evidence of endocarditis on May 10th, six days after the patient was admitted to the hospital. You will notice that the murmur heard over the body of the heart is described as having a different character from that heard at the apex. That is not uncommon. The difference in character at the apex and over the body of the heart is explained by the fact that the conditions in different portions of the heart are such as to give rise to different sounds. The evidence of endocarditis, then, in these cases, is complete.

#### PERICARDITIS.

I will now speak of the physical signs and some of the symptomatic phenomena attending the development of pericarditis. This I will also do in connection with a case.

Pericarditis, as an idiopathic affection, is one of the rarest of diseases. It occurs most commonly in connection with acute articular rheumatism. It occurs not infrequently in connection with Bright's disease, and also with pleurisy and pneumonia. It rarely occurs in other connections, and in making a diagnosis these points in etiology may render valuable assistance.

This patient is just recovering from an attack of acute articular rheumatism. The present attack was not preceded by exposure of any kind whatever. Previous to his admission to the hospital he suffered from pain under the left nipple, and over a circumscribed area confined to the precordial region. The pain became severe and embarrassed respiration, and it is probable that this symptom indicated the commencement of the pericarditis. His joints were swollen and painful, but his ride to the hospital in the ambulance

cured him almost entirely. By way of parenthesis I may say that the case illustrates the benefit which may follow the use of methodic friction. For example, if you will lubricate the hand well, and then begin, with the slightest possible pressure, to rub a joint up and down, gradually increasing the pressure and continuing the rubbing for ten or fifteen minutes, you will find the patient will bear all the force you can put on, and after continuing it for some time the localized pain will be notably relieved. That fact may serve to explain this man's experience in the ambulance.

When this man was admitted to the hospital there was heard over the base of the heart a harsh, rubbing, double friction sound; the same sound was heard at the apex, although less distinctly. The same sound is still present, but it is not so loud as when the patient was first admitted. Prior to the effusion of liquid into the pericardial sac, this murmur is the characteristic physical sign of pericarditis, and fortunately for diagnosis, it is uniformly present. When this sign, therefore, is present in connection with symptoms denoting pericarditis, you may be quite positive in your diagnosis. There is one liability to error which it is well to bear in mind, and that is in some cases of pleurisy or pneumonia with pleuritic inflammation, the movements of the heart may cause a rubbing against the roughened pleural surface, and in that manner give rise to a cardiac pleural friction murmur, which may be double or single.

It is further noted in the history of this case that a soft, blowing murmur is heard with the first sound at the apex, but is not conveyed in any direction. We have then, in addition to the friction murmur, indicating the presence of pericarditis, a murmur which is evidence of endocarditis. This fact leads me to say that when we have rheumatic pericarditis we always have rheumatic endocarditis. The patient was placed under treatment by the use of salicylate of soda.

April 7th, four days after admission, friction sound diminished in intensity. April 11th, fluid in the pericardium increased in quantity. What are the signs which indicate the presence of fluid in the pericardial sac? The to-and-fro murmur limited to the precordia often, but not always, disappears. The diagnosis, then, in this stage is based on signs which indicate the presence of fluid. If the effusion is moderate, the effect is to raise the apex of the heart, and the apex-beat may be felt in the fourth intercostal space and removed to the left of its normal situation.

The power with which the apex is brought against the chest-wall is diminished, and the impulse is always feeble; it may be lost entirely, and usually is, when the amount of liquid effusion is considerable or large. Sometimes a feeble impulse can be obtained by bending the body well forward, when otherwise it would pass unrecognized. If we listen to the heart, after liquid effusion has taken place into the pericardium, we find that the sounds are feeble and distant; the first sound is particularly enfeebled. It loses all its normal character and becomes, like the second sound, short and valvular in character.

Weakness of the first sound, distant and valvular in character, are the characteristics of the first sound of the heart when fluid effusion has taken place in the pericardium.

Another sign indicating the presence of fluid is flatness upon percussion over an area corresponding to the size, situation, and form of the pericardial sac. When the pericardial sac is filled with liquid without being dilated, it forms a pyriform tumor within the chest, the apex of which raises nearly to the sternal notch; the base is at the sixth or seventh intercostal

space; the right lateral border is somewhat beyond the right margin of the precordia, and the left lateral border is considerably beyond the nipple. Within this area there is notable dulness or flatness upon percussion, together with absence of respiratory murmur and vocal resonance. It is by means of these signs that we are able to mark out the boundaries of this pyriform tumor upon the chest. When the quantity of liquid effusion is only moderate, the sac being only partially filled, the same physical signs are present, but we do not get the peculiar shaped tumor. In some cases in which the quantity of fluid in the pericardial sac is very great, flatness upon percussion is present over the greater part of the anterior aspect of the chest. The increase or diminution of liquid in the second stage of pericarditis may be determined by percussion and auscultation. When the quantity is much diminished, the friction murmur, if it has disappeared, returns and remains constant until the pericardial surfaces become agglutinated. Not infrequently, when the pericardial sac contains a large quantity of fluid, the friction murmur can be heard if the precordia is auscultated while the body of the patient is bent forward. In some cases the pericardial friction sound can be heard throughout the entire course of pericarditis without change in the position of the body of the patient, although there may be a considerable quantity of fluid in the pericardial sac. If, therefore, we find a pericardial friction sound in connection with other symptoms, we have the evidence upon which to base a diagnosis of pericarditis; and if the friction sound disappears, the first sound of the heart becomes distant and valvular in character, and there is notable dulness or flatness upon percussion over the precordia, we have the evidence upon which to base a diagnosis of pericarditis with effusion of liquid into the pericardial sac.

These, then, are the important physical signs by which you will recognize the presence of endocarditis and pericarditis, and if they are thoroughly studied and carefully applied you will have no great difficulty in arriving at a correct diagnosis.

## Original Communications.

### A CONTRIBUTION TO THE THEORY OF DYSMENORRHOEA.

By WILLIAM B. NEFTTEL, M.D.,

NEW YORK.

IN 1871 I published the first case of dysmenorrhœa successfully treated by galvanism,\* and reported other cases in Brown Séquard's Archives.† Since that time a very large number of similar cases have confirmed the beneficial effect of the galvanic treatment in dysmenorrhœa. A constant current of considerable intensity is directed chiefly towards the genito-spinal centre, discovered by Budge in the spinal cord (situated somewhat above the lumbar enlargement), and a current of moderate intensity towards the medulla oblongata. No local treatment of the womb is resorted to.

In the majority of my cases the dysmenorrhœa was accompanied by various morbid conditions of the womb, viz.: chronic inflammation, ante-flexion, retro-flexion, stricture of the cervix, etc. In some cases,

† Nefttel, Clinical Notes on Nervous Diseases of Women, p. 375.

however, no displacement or any structural disease of the uterus could be detected. These latter cases presented the greatest interest as regards the theory of dysmenorrhœa. The fact that dysmenorrhœa of the intensest kind and of long standing may exist occasionally without any organic or mechanical derangement of the uterus and its adnexa, proves conclusively that dysmenorrhœa belongs to the class of the so-called functional diseases, being analogous to other visceral neuralgias. Therefore the mechanism that produces the phenomena of dysmenorrhœa must be essentially the same, however different may be the uterine disorder complicating it, and depends upon some nervous, probably spasmodic affection of the uterus. This mechanism I have endeavored to explain in the following manner: an irritation originating in the uterus is propagated through its sensitive nerves (the sacral nerves) to the nervous centre, whence it is transmitted to motor nerves (plexus uterinus), which produce the spasmodic contraction of the uterus. Usually the irritation takes place on the mucous membrane of the uterus, and is caused by the pressure of the accumulated menstrual blood, the free escape of which is impeded.

It is evident that a strictured condition of the cervix, whether resulting from flexions, versions, or chronic inflammations of the womb, is favorable for calling forth that irritation with the subsequent reflex-contraction. But generally these structural derangements, unless they have reached an unusually high degree, do not by themselves produce the phenomena of dysmenorrhœa, because the tissues are sufficiently elastic to admit the uninterrupted flow of uncoagulated blood. In order to produce dysmenorrhœa, it is requisite that there should exist an increased irritability either of the nervous centre, or of the sensitive nerves, or of both. Whenever, therefore, such an increased reflex-irritability exists, a spasmodic stricture of the cervical canal is likely to take place, and impede the free passage of the menstrual flow, even without the presence of any structural uterine affection, though this latter complication must undoubtedly aggravate the dysmenorrhœa. This assumption is corroborated by the well-known fact that frequently persons affected with chronic inflammations, flexions, versions, etc., do not at all suffer from dysmenorrhœa.

Whether this theory is correct or not, I leave to further investigations to decide; but meanwhile the galvanic treatment of dysmenorrhœa based by me on this theory has proved entirely successful, even where all other methods, including the most efficient surgical ones (incision of the neck, sponge-tents, etc.) had utterly failed to relieve the disease. It is impossible in a brief article to discuss all the important facts bearing upon this subject, and I therefore restrict myself at present to pointing out the neurotic nature of dysmenorrhœa, and recommend its treatment by galvanism.

As illustrations I select the two following cases, both being of long standing, examined by a gynecologist, in whose diagnosis no error could be admitted as regards the morbid condition of the genital organs, where no other remedies but galvanism were employed, and which resulted in a complete and lasting recovery:

Mrs. W., 28 years old, of medium size, very anæmic and emaciated, married seven years, but sterile. Soon after her marriage she took a cold bath, not knowing that the menstruation had already appeared; it ceased earlier than usually, and was altogether less copious. The next period was exceedingly painful, and since that time the patient has suffered from intense dysmenorrhœa. At first she remained in bed

only during the monthly periods, which were gradually becoming more profuse and more painful. Soon, however, she commenced to suffer also during the intervals from frequent headaches and a constant backache, until she became a confirmed invalid, passing the greatest part of the time in bed. For seven years she was under the constant care of most eminent gynecologists, and subjected to a variety of internal medications and local treatments—among the latter may be mentioned sponge-tents and incisions of the neck of the womb. Notwithstanding these efficient methods of treatment, her condition continued to grow worse in every respect; it became necessary to keep her under the influence of anodynes during menstruation, while during the intervals nothing could relieve the excruciating pains in the head and back. Her last physicians assumed the existence of a spinal disease complicated with an organic affection of the heart, as she had a great deal of palpitation, with a loud systolic murmur, and an irregular pulse. In the winter of 1873 she placed herself under the care of Dr. J. Marion Sims, who had the opportunity of observing her during three months. Having exhausted all the usual means without avail, Dr. Sims, to whose great kindness I am indebted for a number of most interesting cases, referred the patient to me for galvanic treatment of dysmenorrhœa, the backache and irregular action of the heart having been considered incurable by all the physicians who had treated her.

February 20, 1874, I examined the patient for the first time in the presence of Dr. Sims. She was very weak, emaciated, and could not leave her bed. The skin, and especially the visible mucous membranes, were exceedingly pale. She complained of headache and of pains in the sphere of different nerves (occipito-brachial and intercostal neuralgia, sciatica), but more especially of excruciating backache that had never left her during the last seven years, depriving her of nights' rest, and preventing her from walking; the digestion was impaired, and she had no appetite. With the approach of the monthly period all the morbid symptoms were exacerbated and culminated in the intensest dysmenorrhœa, necessitating the use of anodynes, which, however, did not entirely relieve, but merely mitigated the excessive pain. After the period a high degree of prostration remained, from which she scarcely had time to recuperate before the appearance of the next period with all its morbid symptoms. Her pulse was small, accelerated, the heart's action irregular, with a loud systolic murmur; the spine exceedingly tender to the touch, especially the cervical and lumbar portions, the latter not bearing the slightest touch. Dr. Sims informed me that there was "flexure anteriorly at os internum, cervix indurated (a grizzly condition), small, projecting into vagina at proper angle; os small, canal narrow." He had incised the cervix bilaterally to os internum, "incision anteriorly at os internum at point of flexure," but the operation did not relieve the dysmenorrhœa or improve the general health of the patient.

My diagnosis was general anæmia in a chlorotic person, with neuralgic affections in the sphere of different nerves, caused by the anæmia of the brain and spinal cord. The dysmenorrhœa I considered as a neurosis, and the ante-flexion as a mere complication of the visceral neuralgia. The first and apparently the most important indication was to improve the anæmic condition by the use of preparations of iron and a tonic régime, and at the same time to treat the neuralgic affections with the galvanic current. The patient at once warned us that she had a peculiar idiosyncrasy against iron, and that every physician who had tried

it had soon to discontinue its use on account of the most unpleasant symptoms it invariably called forth. However, the indication being so rational, I prescribed small doses (two grains, and afterwards one grain) of iron byhydrogen, but very soon had to stop its use; the headaches became unbearable, the face flushed, the mouth dry, with loss of appetite and other symptoms resembling those of fever, although the temperature was scarcely increased. I refrained also from giving her quinine or other tonics, as they likewise had been vainly tried many times, and, therefore, resorted to the galvanic treatment, excluding every other medication. The difficulty of applying the current, on account of the excessive tenderness of the spine, could only be overcome by beginning with the weakest possible currents, increasing the intensity with the greatest care, and avoiding sudden and large fluctuations of the current density by means of a rheostat, intercalated as an accessory current. This treatment was continued daily, and under its influence the general health of the patient rapidly improved, the appetite, digestion, and sleep became normal, the neuralgic pains disappeared to a great extent, and she could walk in the open air, even during the most inclement weather, though the backache continued as before. March 31st, the menstruation appeared with considerably less pain, and this lasted only six hours, so that the patient, without any anodynes or other remedies, did not have to remain in bed or even indoors, but continued during the whole period her daily walks and galvanic treatments. Under the influence of these daily treatments the next period was entirely painless, and the backache gradually disappeared altogether. In order to prevent relapses, but more especially because the patient was afraid to return to her home (Virginia) too soon, she remained under treatment for a third month. The change in her condition was most remarkable: the external appearance was healthy, she felt strong, could walk long distances; the sleep, appetite, and digestion became normal, and bowels regular. Her general health still remains excellent, and she is perfectly free from dysmenorrhœa and backache. Her husband, in his last letter, dated October 21, 1876, writes, "I am sure you will be glad to hear that she has steadily improved since she left you three years ago next spring. You remember the awful headaches with which she used to suffer, and the agonizing pain in her back. Now she never has either, etc." Last November Mrs. W. was in New York, and presented herself to Dr. Sims, who convinced himself of her complete and permanent recovery from dysmenorrhœa and backache.

Though I consider electricity as invaluable in the treatment of nervous diseases, I mostly employ it in combination with other dietetic and pharmaceutic remedies. In this particular case, however, the efficacy of galvanism alone had to be tested, at the exclusion of all other medications. The facts that every known method had been unsuccessfully tried before, and that the patient still remains in perfect health and menstruates normally, admit but of one conclusion—that a radical cure of dysmenorrhœa has been effected by means of the galvanic treatment. So far this case could have served as an *experimentum crucis* as regards the value of this method. It is, therefore, much to be regretted that no examination of the sexual organs could be made after the termination of the treatment, the patient declining such an examination.

The following case, which I report here in a condensed form, presents a special interest only as regards the theory of dysmenorrhœa, inasmuch as it reveals the neurotic nature of the affection.

Miss E., æt. twenty-nine, has inherited a neuropathic constitution, her father having died from softening of the brain. She always suffered from dysmenorrhœa, and though well nourished and looking tolerably healthy, was frequently subject to headaches, flushed very readily, and often had fainting fits, especially during the menstrual pains. The dysmenorrhœa was always accompanied with a sensation of cold in the extremities, with congestion to the head and other vaso-motor phenomena. Dr. Sims found ante-flexion of the uterus, and proposed an operation (incision of the cervix), as nothing else could relieve her dysmenorrhœa. She was afraid of an operation, and, therefore, Dr. Sims kindly referred her to me for galvanic treatment, October 23, 1874. As all the usual remedies had been tried without benefit for so many years, I concluded to observe the effect of the galvanic treatment, unsupported by any other medication, in order to obtain and demonstrate the uncomplicated result of the galvanic treatment of dysmenorrhœa. In the progress of this case there was nothing of particular interest which would require any special notice. Under the influence of daily galvanic treatments the menstruation appeared November 5th, with considerable pain, which, however, lasted only a few hours. The next menstruations (Dec. 5th and 31st) were entirely painless. Moreover, she was relieved from the headaches, fainting fits, coldness of extremities, and other morbid symptoms within the vaso-motor sphere, and left New York January 12, 1875, in a perfectly healthy condition, which still continues. Last fall, on her way from the Centennial exhibition, she visited New York, and called on Dr. Sims, whom she informed that she is permanently cured of the dysmenorrhœa and other morbid symptoms by the galvanic treatment. Dr. Sims, referring to this case in a note to me, writes: "On examination I found the uterus of the same shape and size, and with the same relations as when I saw her before (the galvanic treatment). But there was no congestion of the cervical mucous membrane as before."

This examination proves, beyond any possibility of doubt, that the dysmenorrhœa, which lasted in our patient from the first appearance of catamenia, over fifteen years, and could be ascribed to the existing structural disorder of the uterus, has been permanently cured by means of the galvanic current, notwithstanding the persistency of the organic affection. The circumstance that a congestion of the cervix was not noticed several years after the galvanic treatment can evidently be left out of consideration. Such congestion of the cervix must be ascribed to the result of dysmenorrhœa rather than to its causes.

In the opinion of unprejudiced observers one single *positive* fact is more valuable than a large number of negative ones, and I can consider, therefore, the above related case as an additional proof that dysmenorrhœa is essentially a nervous affection (visceral neuralgia), though it is frequently complicated by structural or mechanical derangements of the uterus.

From a large number of cases of dysmenorrhœa I selected these two, being the only cases referred to me, and examined by Dr. Sims.\*

I reserve for a future occasion to give further details with reference to other points of interest, and will merely mention that with the dysmenorrhœa disappear also the congestions of the pelvic organs, especially the chronic inflammations of the uterus, and the general health improves.

\* A third case lately sent to me by Dr. Sims is excluded from consideration, because sufficient time has not yet elapsed since the galvanic treatment.

The advantages of the galvanic method of treatment of dysmenorrhœa are so obvious that it is scarcely necessary to mention them. Besides affecting favorably the general health, there is one point which above all will be appreciated by the physician and patient. This method does not require any local treatment of the womb, a circumstance of high importance in the treatment of young women, and especially where there exists a morbid irritability of the sexual organs.

NOTES UPON THE SURGICAL ANATOMY OF THE OBTURATOR ARTERY.

THE DIFFERENCE OF ITS RELATIONS IN THE MALE AND FEMALE, WITH A CONSIDERATION OF ITS IMPORTANCE IN THE OPERATION FOR RELIEF OF FEMORAL HERNIA.

(Deduced from twenty-seven consecutive dissections of the arteries in the male, and twenty-six in the female pelvis.)

By JNO. A. WYETH, M.D., AND WILLIAM L. WARDWELL, Esq.,

OF NEW YORK.

In its distribution the *obturator artery* is simple and constant; in its origin and relations there is no artery in the human body which presents so many vagaries. In support of this last statement it will suffice to quote from some of the standard text-books the different opinions of different anatomists upon this artery.

Quain gives its origin as "usually from the posterior trunk of the *internal iliac*, not unfrequently from the *epigastric*."

Sappey takes a different view, and says "from the *hypogastric* (*anterior trunk of internal iliac*), sometimes from the *external iliac*, rarely from the *femoral*."

Leidy is of the opinion that it "is a branch of the posterior trunk, and often a branch of the anterior trunk of the *internal iliac*."

Wilson gives it "from the anterior trunk; frequently from the posterior trunk of the *internal iliac*."

Gray agrees with Wilson *verbatim*, adding that "in 2 of 3 cases the obturator arises from the *internal iliac*, in 1 of 3½ from the *epigastric*, in 1 or 72 by two roots from both vessels."

Luschka, "from anterior trunk of *internal iliac*; occasionally from external iliac, *epigastric*, or *femoral*."

Velpeau writes: "An examination of several thousand cadavers does not permit me to say that the *obturator artery* comes from the *epigastric* in 1 of 3, nor 5, nor 10, but only 1 in 20."

Tiedemann says, on the other hand, that "you may expect to find the *obturator* from the *epigastric* in 1 of 3 cases, this variety being more common in the female than in the male."

In the two following tables I have given the analysis of 53 dissections, made in order to contribute something of certainty to the anatomy of this artery. Thirteen subjects of each sex were chosen, and both sides noted as they were dissected.

It will be seen that in *females*, of 26 cases, the *obturator* was from the *deep epigastric* in 13½ instances; from the posterior trunk of the *internal iliac* in 1½; from the anterior trunk in 11 instances.

In *males*, of 27 cases, it was from the *epigastric* in only 5; from the *posterior trunk* in 1; while from the *anterior trunk* of the *internal iliac* it was derived in 22 instances.

In these cases it is seen that in *females* we may expect to find the *obturator* to be derived from the *deep epigastric* in 1 of 2 cases; in males in 1 of 4½ cases. And, in a total of 61 cases, regardless of sex, the proportion is 20, or 1 in 3.

Tiedemann is the only one of these anatomists who notices the difference between the origin of this vessel in *males* and *females*.

\* The  $\curvearrowright$  to the left indicates the dissections to have been made upon both sides of the same subject; that to the right, that the origin was the same on both sides of the same subject.

NOTE.—In 8 other dissections in which the sex was not noted, this artery came from the *anterior trunk* in 5, from the *posterior* in 1, from the *deep epigastric* in 2 instances.

\* The writer is indebted to Dr. J. Minis Hays for valuable reference in regard to this artery; to "Lawrence on Ruptures," one of the most valuable books on this subject published.

In 160 cases in which Cloquet noted the *obturator* as coming from the *internal iliac*, 87 were in males, 73 in females, showing, as in my cases, the greater tendency of this vessel to come from the *internal iliac* in men.

In 56 cases this same author noted from the *epigastric*, 21 were in males, 35 in females, agreeing also with the dissections embodied in this article, that the tendency of the *obturator* to come from the *deep epigastric* was much greater in *women* than in *men*.

So great is this difference, that the estimates made from both sexes should not be considered, in view of the probable contact with this vessel in femoral hernia.

An examination of the foregoing tables will show that in 19 of 26 subjects this artery was derived from the *same point on the two sides*, showing in this respect a symmetry of arrangement I have not noticed in any other artery of the body.

Femoral hernia being comparatively a rare accident in the male, and the *obturator* artery having a dangerous relation to the *femoral ring* in the male sex in only a small proportion of cases, the surgical interest of this vessel belongs to the opposite sex.

When derived from the *epigastric*, it usually comes off from this artery from  $\frac{1}{2}$  to  $\frac{3}{4}$  of an inch from the origin of the *epigastric* from the *external iliac*. It then turns abruptly down on the outer side of the *femoral ring*, being in intimate relation with the sheath of the *external iliac vein*, and thus makes its way to the *obturator foramen* in such a manner that it would be exceedingly difficult for the intestine, descending to form a *femoral hernia*, to insinuate itself between the *iliac vein* and the *obturator* artery, so as to loop this latter vessel around the hernia. This danger will be greater as the *obturator* is distant at its origin from the *external iliac*. However rare this double accident may be (femoral hernia, with the *obturator* artery looped around it), yet, as it can and has occurred in several instances, the surgeon should proceed in every instance as if he supposed this accidental arrangement existed.

When the stricture is so situated that Gimbernat's ligament requires division, the point of the be-pointed bistoury should be kept hard pressed against the surface of the *os pubis* to which this ligament is attached, and, as is advised by one of the most eminent American surgeons, "the ligament should be divided without any sawing motion."\* It is evident that, if the cutting edge of the knife is not pushed beyond the ligament into the pelvis, the artery will not be divided.

I have noticed that the *obturator vein* is in relation to the femoral ring in a much larger proportion of cases than the artery, it being often double, one going to the *internal iliac*, the other to the *external iliac vein*, when the artery was from the *anterior trunk* of the *internal iliac* alone.

Deductions: 1st. That anatomists giving the origin of the *obturator artery* from the *posterior trunk* of the *internal iliac* are *positively wrong*, the vessel not originating from this point in more than 10 per cent.

2d. That in females it will be derived from the *deep epigastric* in one of two, or two and one-half cases.

3d. That in males it will be from the *deep epigastric* in one of four or six cases.

4th. That the *obturator vein* is found to empty into the *external iliac* or *epigastric vein* in a much greater proportion of cases than the artery is found to originate from the *epigastric* or *external iliac*.

5th. That the advice, to "feel for the pulsation of this artery before cutting Gimbernat's ligament."\* (as is frequently given), seems unnecessary, since the insertion of the finger through the constricted canal, completely filled by the intestine, *that has for this reason become strangulated*, is impossible until after the section is made.

6th. That, although the conditions in which the *obturator artery* is found to the inner side of a femoral hernia rarely exist, the operation should be made with every regard to this abnormal arrangement.

NOTE.—In one instance I have seen the *obturator* a branch of the *epigastric*, and this latter a branch of the *profunda femoris*. This specimen is the property of the Wood Museum of Bellevue Hospital, and is not included in these notes, on account of its being so unusual.

44 WEST 27TH ST., Sept., 1877.

## Progress of Medical Science.

SYPHILITIC DISEASE OF THE INTERNAL EAR.—In a paper published in *Virchow's Archives*, Prof. Moos briefly recapitulates the little that is thus far known about the pathologico-anatomical changes in cases of deafness due to syphilis, and then gives the details of a case that came under his own observation. The case was one of secondary syphilis, in which dizziness, annoying tinnitus aurium, and osteoepic pains in the skull were complained of. The hearing was rapidly destroyed. Death. At the autopsy the right external and middle ear were found intact. Sclerosis of the petrous portion of the temporal bone; periostitis in the vestibule, and small-celled infiltration of the membranous labyrinth. Ankylosis of the stapes to the fenestra ovalis. Tunk of the acoustic unchanged. It is evident from this and other cases, that early and rapid loss of hearing is a valuable symptom for the diagnosis of a syphilitic disease of the ear.—*Centralblatt für Chirurgie*, August 19th.

ATROPHY OF THE TESTICLES FOLLOWING MUMPS.—At the meeting of the *Société Médicale des Hôpitaux*, on August 10th, M. Lereboullet presented a scoldier, twenty-two years of age, who had had an attack of parotiditis four months before. His genital organs were then well developed. Four days after the mumps set in, he was seized with a pretty severe double orchitis, which lasted three days. The swelling of the parotids persisted for a few days longer and then disappeared. About three weeks later, the testicles were found to be undergoing atrophy, and at the present time they are only about as large as almonds. Simultaneously with the atrophy of the testicles, the mammary glands became enlarged, and the development of hair on the chin was arrested. The chin of the patient is now as smooth as that of an infant, but the hair on the pubis is as strong as before. M. Render stated that he had met with a case of atrophy of the left testicle, with hypertrophy of the mamma on the same side.—*La France Médicale*, August 22d.

TRANSFORMATION OF SERO-FIBRINOUS PLEURISY INTO EMPYEMA.—M. Dieulafoy has examined microscopically the fluid withdrawn from twenty-two cases of pleurisy, and has found that even in the mildest cases this fluid invariably contains from 1,500 to 2,000 red blood-globules to the cubic millimetre, although it may not present the slightest coloration. When the fluid contains from 6,000 to 7,000 blood-globules

\* Hamilton's System of Surgery, p. 743.

\* Holmes' Surgery, Vol. IV., p. 773.

to the cubic millimetre, it has a slightly reddish tinge. Relying on these facts, M. Dieulafoy thinks it probable that empyema is, originally and histologically, a hemorrhagic pleurisy. When the pleuritic fluid contains from 2,500 to 3,000 red globules, the case should be regarded as one of simple pleurisy; but when the red globules are more numerous, it is very probable that the affection will develop into an empyema. He thinks that in these cases, as in pneumonia, the period of suppuration is preceded by one of congestion and extravasation; the red globules diminish in number or disappear, and at the same time the white globules increase in number, until finally the fluid is purulent rather than hemorrhagic. M. Dieulafoy does not claim that the presence of red globules in large numbers in the pleural fluid necessarily causes it to become purulent; there are true hemorrhagic pleuritis which never become empyemas. The duration of the period of congestion and extravasation is unknown; in some cases it seems to be from five to eight days, or even longer. In conclusion, M. Dieulafoy sums up with the statement that, aside from the true hemorrhagic pleuritis which are symptomatic of cancer or tubercle, there are others which are originally hemorrhagic from a histological standpoint, but have a special tendency to become purulent altogether independently of the operation of thoracentesis.—*La France Médicale*, August 15th.

**A CASE OF IMPERFORATE ANUS WITH FISTULOUS OPENING INTO THE BLADDER.**—On April 11, 1876, a male child, two days old, was brought to Mr. Rowan, at the Melbourne Lying-in Hospital. On examination an imperforate condition of the anus was found; there was no depression or mark to indicate its usual position. The abdomen was distended, tympanitic, and very tender. On the next day chloroform was administered, and an incision was made in the centre of the fundament, and after cautiously dissecting to a depth of two and a half inches, the rectum was reached. An opening was made into it, and a large quantity of meconium and flatus escaped. The wound was kept open for a week with oiled lint, and a large bougie was subsequently passed every second or third day. Mr. Rowan shortly afterwards lost sight of the child, but it was brought back to him on the first of last February, in a worse condition than in the preceding April. The bougie had not been passed for three months, and for two months the child had passed nothing by the natural passage, all the motions escaping through the penis until the previous day, when the foreskin became so narrow that the child could not pass even water without great difficulty. Examination showed that the anus was closed about an inch from the orifice, and revealed in addition complete phimosis. Circumcision was performed, and a few days later the former passage into the rectum was reopened and enlarged sufficiently to allow the finger to be passed in. The rectum was found filled with hard feces, which did not come away until the next day. After the operation the finger was passed every day, and at the present time the canal seems perfect. Mr. Rowan thinks that a second operation would not have been required in this case, if he had made the opening large enough at first to allow the finger to be inserted easily. The fact that defecation occurred through the bladder and penis for two months without causing cystitis or urethritis, is curious.—*Australian Medical Journal*, March, 1877.

**BEWARE.**—A city physician writes that his office has been invaded by a sneak-thief and sundry professional articles removed.

#### NOTES OF PRACTICE, AND PECULIARITIES OF TREATMENT.

**LEFT HEMIPLEGIA—APHASIA—QUESTION WITH REFERENCE TO THE CAUSE—REASONS FOR BELIEVING IT TO BE OF SYPHILITIC ORIGIN.**

A MALE patient, *et.* 32 years, had enjoyed very good health up to seven months ago, when he noticed that paralysis was slowly affecting the left side. He had suffered from headache continuously during the four weeks immediately preceding the appearance of the paralysis. The fact that the man was only thirty-two years old was regarded as evidence in favor of the syphilitic origin of his hemiplegia. It was said that, when hemiplegia occurred in persons under thirty-five years of age, in seven out of ten cases it would be found to be due to chronic endarteritis dependent upon syphilis, or due to embolism. If due to embolism it is not preceded by headache. Hemiplegia, when of syphilitic origin, it was said, is almost invariably preceded and is usually followed by headache; whereas, when the hemiplegia depends upon embolism, it comes without warning. In cases of syphilitic endarteritis terminating in hemiplegia it was said there were three different classes of symptoms.

*First.*—There is absolutely no tension whatever to the pulse.

*Second.* with reference to pain. Severe pain in the head is a pretty sure indication that you have to deal with trouble in the periosteum or in the meninges of the brain; that is, it is at the outer surface of the brain where the disease is mainly located.

Syphilitic endarteritis, on the other hand, although accompanied by headache, does not give rise to the agonizing pain which is present in any of the forms of inflammation affecting the periosteum or the coverings of the brain. Instead of that, the headache is of a dull and persistent character, is much more likely to be accompanied by loss of memory, cramps in the legs, inability to sleep through the night, and a sense of mental inactivity. These are the symptoms of syphilitic endarteritis preceding hemiplegia.

*Third.*—Symptoms accompanying the presence of tumors—gummata. These symptoms will vary exceedingly according to the situation of the tumor. They are not apt to be accompanied by special headache. On the other hand, there is more likely to be slight paralysis somewhere about the face; affecting the muscles of the eye or those about the mouth; or perhaps some action of the fingers is affected, etc. But one symptom, it was said, is always present—namely—a pulse without tension. If, therefore, a patient appears having slight paralysis of some of the muscles of the face, etc., examine the pulse, and if it be found to be without tension, the suspicion should at once be aroused that there is syphilis behind all the symptoms.

Another interesting feature in the case was the fact that there was aphasia associated with the left hemiplegia, the aphasia continuing three weeks after the paralysis appeared. The treatment was iodide of potassium; and to do much good in cases of syphilitic hemiplegia it was believed to be necessary to administer it in large doses, *grs. lx.*, *t. i. d.*, and increased until, perhaps, *grs. 240* are given three times a day.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

Wm. Wood & Co., No. 27 Great Jones St., N. Y.

New York, October 6, 1877.

## MEDICAL REGISTRATION.

WITH every issue of the *Medical Register* there are more or less complaints concerning the omission of names. This is to be expected, as no earthly tribunal is believed to be immaculate. The fact is so well acknowledged that there is always a reasonableness in according to every suspected criminal the right to a fair trial and a proper appeal.

In making the above preliminary remarks it is not our intention to question the decision in any individual case, but to refer, in a general way, to some of the principles involved in the present system, and their liability to abuse. We approach the subject with the full conviction that all attempts at perfect medical registration are beset with difficulties, the majority of which are not even imagined by those who have given no attention to them. Indeed, very many practical men deem these obstacles so great that they have been and are still discouraging every effort in that direction. We do not believe that these impediments are absolutely insurmountable, but at the same time we are convinced that medical registration, for all practical purposes, can approach a high degree of perfection. How the latter point can be attained is the question which involves all others connected with it. Perhaps there is no shorter way of arriving at any conclusions upon the subject than in learning some of the lessons which have been offered by the experiences of the Medico-Historical Society of this city. Until the gentlemen composing this organization took the matter in hand, no attempt had ever been made to create a reliable register of medical practitioners in this city. As this register was the first, and is by all odds the best of its kind anywhere in the United States, it can with justice be considered the type with which all others may be compared. That this annual is generally considered authoritative is a great compliment to the arduous labors of those

who have aimed to make it so. There is hardly a doubt in the minds of the profession that the editor and committee do their utmost to insure accuracy; but that they may be mistaken in their decisions and do injustice to some individuals, is not only possible, but highly probable. The suspicion of the latter is not lessened by the fact that the decision in any given case is considered final, and is made by a tribunal which, however excellent, is self-constituted, and is practically perpetual. With unprincipled persons the temptation to do injustice to individuals would be almost irresistible, and even with the best of men a long acquaintance with heavy responsibilities may, in the end, beget a sufficient indifference to their claims to amount to positive and culpable neglect of duty.

Then, again, there is danger that what are really the interests of the profession at large will degenerate into those of a mere ring. Obnoxious as is this idea to those who, like ourselves, have confidence in the integrity of the editor of the *Register* and of the gentlemen composing his committee, it is being constantly brought up by such as believe themselves to be unjustly treated. Appreciating how hard it is to convince any individual that a judgment against him is just, we nevertheless add weight to any argument in his defence based on the acknowledged appearance of evil on the part of his judges.

These are, if not all, at least some of the more important defects of our present system of medical registration. We are speaking of them as matters of principle independent of individuals. The fact that trustworthy individuals may possess a power liable to be abused by others is almost as strong an argument for a change as if the latter were already in authority. The exponents of a principle are accidents of circumstance, but the principle itself is always positive and unchangeable. If, then, the principle is so defective as to depend more upon its exponents than upon itself, the sooner it is altered or strengthened the better.

But it is easier to find fault than to suggest a remedy. In regard to this particular question, more than the usual difficulties are in the way. The attempt to overcome them involves a compromise between what we already have and what we may expect, rather than what we would like to have.

At present, medical registration, in this city at least, is a private enterprise. The *Medical Register* itself is private property, and because it has been well managed, and has gained the confidence of the profession, it has succeeded. The association of a few interested in its success was an inevitable circumstance of its inception and development. The editor, and the committee of the Medico-Historical Society, have done all the work, and are entitled to use their material as they please. This is a question of individual rights with which no one cares to interfere.

But naturally the profession, now that medical registration has become an established fact, are more

interested in the further and more perfect development of the system than in the individuals who have been and are still the practical expounders. Since the *Register* is considered an authority as to the standing of individuals in the profession, every one who desires to be placed right upon the record is interested in knowing for what reason his name may be omitted. The very fact that such an anxiety is shown by any physician should stimulate the proprietors of the annual to give every satisfaction to the malcontents. If their machinery is acknowledged to be powerful, they should use it in the charitable effort to elevate a weak brother, rather than run any risk in crushing him. The real difficulty, however, in the way of reform is that the enterprise is a private one, and that professional opinion must use its force in the direction of suggestion rather than compulsion. Whether there be any real grounds of complaint or not against the parties whose names are omitted, it would seem to be a matter of policy as well as justice to refer the matter to some other tribunal. This might appear to be straining a point to gratify a very few men who are acknowledged to be on the doubtful list, but we think that the end would justify the means; at least it would do away with the necessity for the annual growl against the ring of the *Medical Register* and of the Medico-Historical Society. It seems no more than right, if, when there is a possibility of committing an error of judgment in a matter which is now considered of such vital importance to individuals, that there should be another court to which an appeal might be made. Naturally, a committee from the County Society would be the most representative, as well as the most competent to decide disputed points. The fact that the complaining ones are in such small minority is the best reason why extraordinary pains should be taken to show fair play. Professional opinion has been cultivated to such a point that, when a name is omitted, either accidentally or purposely, from the list, there is a lurking suspicion that something is wrong with the individual rather than with the *Register*. While there are numerous exceptions to this rule, there are plenty of men who feel that they would have a better show if judgment of their case were not left in the hands of a close corporation. In view of the importance of the decision, and the weighty individual interests at stake, it would appear that the registering committee should, for the sake of their own protection, gladly divide their responsibilities with some other party. As we said before, however, this is a suggestion more than anything else, but we believe that timely attention to it will anticipate what, at no distant day, will be a demand of the profession at large, and conditional with its continued countenance and support.

In looking over the experiences of the past few years, in this or other cities, we have proved to us the importance of medical registration. This is none

the less so from the fact that the undertaking is the result of private enterprise. As it is, however, it proves that when carefully, persistently, and accurately carried out, it can command the respect and influence of all good men. The question arises in this connection why the same success cannot be assured to the different county societies, and through them to the respective societies of the State. Beyond the area of the latter no particular register can pretend to be trustworthy; but when we consider with how little trouble a yearly list of every regular practitioner throughout the State can be published, we wonder why it has not been done before. If such a register were issued, even in pamphlet form every year, every medical man in the State would be interested in the success, and would be careful to fulfil all the conditions necessary to the appearance of his name and address.

And from being useful to the profession, such a list could be made of value to the public by its official publication in the daily papers. Such a course would be eminently proper, would make no invidious distinction, and would give the public the opportunity of knowing who were the properly qualified medical practitioners in their neighborhood.

#### THE HIGHER MEDICAL EDUCATION—THE BEST INTEREST OF THE PUBLIC AND THE PROFESSION.

THE above was the title of the address, an abstract of which will be found in the column of Medical News of this number, delivered by Professor Wm. Pepper, M.D., before the trustees, faculties, students, and friends of the University of Pennsylvania, on Monday last, on the occasion of the opening of the session of 1877-78, at the University Medical School. That school has determined to lengthen its course to three years, to have a regular gradation of studies with yearly partial examinations, and the examinations for a degree held by an impartial uninterested Board of Examiners, seven in number, selected from the whole medical and clinical faculty.

The address, which was a thorough, thoughtful, and comprehensive survey of the whole subject of medical education in its American phases—and which we understand is to be soon published in pamphlet form, together with some tables of statistics—went over the ground so thoroughly as to consider all objections and leave nothing unsaid in favor of the reform instituted.

When the matter came up for criticism in Philadelphia last spring, the chief argument against the proposed change was that no reform was called for, as the standard of medical education in this country was fully up to our wants and all that our present stage of development rendered needful. The doctor has completely exploded this myth by a reference to "Aitken's General American Register," published in

1773, in which the requirements for admission to and graduation from the University Medical School are described. According to this, the applicant for admission, unless a bachelor of arts, was obliged to pass a preliminary examination. There were two degrees. M.B. was given after a year's course in anatomy, materia medica, pharmacy, chemistry, and theory and practice of medicine, apprenticeship in the office of a practitioner, and attendance upon clinics. M.D. was not given until three years after graduation and upon the presentation and defence in public of a Latin thesis upon some medical subject. That was the standard of 1773! Since that time the status of medical education in America has been steadily and persistently settling down. As regards the other objection, that the new system would over-educate physicians and render them impracticable, the experience of European schools and that of Harvard in this country prove its manifest absurdity.

Having pretty thoroughly and convincingly answered all objections, the doctor, after stating the present state of the question abroad and our own backwardness, proceeds to call attention to the three principal evils of the present system: the immense over-production of medical men in this country, the lowering effects of the present state of affairs upon the tone of the profession as shown in the growth of humbug and quackery, and last of all, the growing evil of the dispensary system. The address closes with a petition for interference on the part of the State legislatures and the initiation of regular medical legislation.

The whole tone and thought of the oration meets our most cordial approval. The evils of the too rapid overflow of medical men are everywhere apparent, chiefly so in the manifest inability of the vast majority of these graduates to find any means of supporting themselves in an already overcrowded profession. Still, in spite of all these obstructions, the medical schools continue to increase and multiply, and in such unlimited competition, as the doctor says, that the one succeeds best who charges the lowest fees and graduates its students at the shortest notice.

The need of reform is absolute and immediate. The way which the Philadelphia school has chosen is the right, if it is a narrow way, and must inevitably, and that at no very distant time, be adopted by every institution which appreciates the responsibilities of its graduates, and is cognizant of the educational requirements of the age.

**SOLUTION OF QUININE FOR HYPODERMIC USE.**—Dr. James E. Morris, of Belleville, Texas, sends the following formula for a solution which in his practice has operated satisfactorily. Bromide of quinia dissolved in alcohol, grain for minim; to this solution water can be added to any dilution desired. It acts promptly and leaves no scar. One of the advantages claimed for this solution is that the alcohol prevents the development of fungi. It is readily absorbed usually, and has a peculiar quieting effect upon the nervous system.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, September 12, 1877.*

DR. E. G. JANEWAY, PRESIDENT, IN THE CHAIR.

#### EXTENSIVE OSTEO-PERIOSTITIS RESEMBLING ACUTE ARTICULAR RHEUMATISM.

DR. A. C. POST presented a sequestrum, removed by operation from the os brachii of a boy aged fourteen years. About a year ago the patient, after exposure to cold, was seized with a severe pain in both shoulders and in one hip. All the symptoms so closely resembled those of acute articular rheumatism, that his physician made a diagnosis accordingly. In the course of time, however, abscesses appeared and communicated with dead bone. When Dr. Post saw the case, during the month of August, there were three or four sinuses in the left arm, penetrating an involucrum extending from near the shoulder to the elbow. Through each of these rough and bare bone was felt, as also through a sinus just below the opposite shoulder, and one in the neighborhood of the left sacro-iliac synchondrosis. The left arm, being most extensively diseased, was operated upon, and the specimen in question was removed from near the elbow.

By a somewhat remarkable coincidence, three weeks after this operation, Dr. Post was called to see a similar case in which a similar diagnosis had been made. This was a boy aged twelve years, who had acute inflammatory swellings occurring at three different joints, viz., the left shoulder, right elbow, and right knee. He was with his father at Long Branch July 1st, and was brought to this city on the 20th of August, and his family physician was sent for, who discovered a large collection of matter just below the shoulder, and evacuated it. The finger introduced into the opening thus made came in contact with dead bone. Dr. Post, having been sent for, enlarged the incision to the extent of two or three inches, passed his finger completely around the bone, and found that the periosteum was detached as far as the epiphysis. That portion, which was an inch and seven-eighths in length, was removed by a chain saw, leaving the epiphysis in the articular cavity. At the end of three weeks after the operation the epiphysis seemed to retain its vitality. The inflammation which affected the elbow was transient, but the knee was still swollen, and was bent at an angle of thirty degrees.

#### CYSTITIS ORIGINATING IN STRICTURE—THE DANGER OF HOSPITAL URINALS.

Dr. Post exhibited also the urinary bladder and kidneys from a patient of the Presbyterian Hospital, who died Sept. 2d, after having suffered for a considerable time with cystitis originating in stricture of the urethra. The mucous membrane of the bladder was thickened and eroded; both kidneys contained abscesses; the right was somewhat atrophied, its ureter being the seat of a stricture, and consequent dilatation above. The patient had considerable incontinence, and was obliged to wear a urinal pouch, his bladder being evacuated at stated intervals by the catheter.

DR. JANEWAY believed that hospital patients were more liable to cystitis than others, for the reason that the urinals were not apt to be thoroughly cleansed, and consequently that there was more danger of bacteria finding their way up the urinary tract. Especi-

ally was this the case when the penis was allowed to soak for any length of time in a urinal pouch. In his service he made it a rule that the urinals should be constantly washed with an ammoniacal solution, so that absolute cleanliness should be insured.

DR. SEBASTIAN concurred in this opinion, and was convinced that, with care in keeping catheters and urinary utensils clean, even in cases of paraplegia, cystitis could be prevented for an almost indefinite period. He was in the habit of using a separate catheter for each patient, and having the instrument constantly under water during the intervals of its continuous use.

DR. BRIDGON remarked that he knew of many private patients who had worn urinal pouches for years without inconvenience. Possibly more than ordinary care was used in keeping them clean. In regard to the specimens of osteo-periostitis, Dr. B. referred to one in his experience which followed small-pox. In that case the knee-joint, one elbow-joint, and one-half of the clavicle were affected. He ascribed the disease to the absorption from the pustules. He had seen a few similar cases in ill-fed children who had suffered from scarlet fever.

DR. POST remarked that there was a suspicion of scarlet fever in his second case.

#### UNEXPECTED DEATH—FATTY DEGENERATION OF THE HEART.

DR. AUSTIN FLINT exhibited a heart which he had not seen before that evening. It was not much enlarged in volume, the valves and coronary artery were sound, and there was nothing found except the gross appearances of a certain amount of fatty degeneration. The history of the specimen was this: Some few days ago, early in the morning, two gentlemen drove in a carriage to Dr. Flint's house, and one of them said that his friend had heart disease, was afraid to walk from the curb to the office, and desired the doctor to come out and examine him. Dr. Flint did not think that there was any special danger in such an undertaking on the part of the patient, and the latter came in the office. The gait was slow and he manifested in manner and in countenance a great deal of anxiety. Dr. F. found the heart palpitating. He satisfied himself that it could not be enlarged, that there was no valvular lesion, and informed the patient accordingly, assuring him that there was no danger, and that he should make his mind easy. He was instructed, however, to come again for another examination, which he accordingly did the day following. At this examination the heart was beating rapidly, the impulse did not give the impression of feebleness, and there was a systolic murmur heard over the body of the heart, but not transmitted beyond the apex. The opinion of the previous day was repeated, and after receiving some general directions the patient left. Dr. F. had an urgent summons in the evening to which he could not respond, and Dr. Perry visited the patient. Dr. F. remarked that there was one circumstance in the patient's history which did not however make the impression upon him which it should, and that was a period of unconsciousness after running upstairs. Dr. Perry obtained this history: The patient during the afternoon was seized with another fit of unconsciousness, which lasted for a few moments, during which time there was marked lividity. Dr. Perry, on his arrival, found the pulse not deficient in force and beating with regularity. He recognized the murmur, but nothing else; gave a favorable prognosis, prescribed an etheral stimulant and left. During the same night Dr. P. was again summoned to find to his surprise his patient moribund,

and with scarcely an appreciable pulse. Of course in a short time the patient died. Dr. Flint, in the absence of any better cause for death, assumed that fatty degeneration existed, and yet during life, notwithstanding careful examinations, no auscultatory evidence of such a condition was found. The case was of interest not only in itself, but as proving that there is sometimes a risk in assuring the patient that there is no danger, and yet even at the risk of a mistake such an assurance should not be denied to them. In answer to questions from members, it was further stated that there was no membranous effusions in the meshes of the columnæ carneæ; that a few weeks before death the patient suffered from shortness of breath.

DR. JANEWAY remarked that fatty degeneration of the heart was blamed for more sudden deaths than it deserved. Especially was this the case in deaths from chloroform, the slightest amount of extra fat upon the surface of the organ being seized as the immediate cause of death.

DR. M. P. JACOBI referred in this connection to a specimen of heart presented last spring, in which the cause was not explained by any distinct pathological reason; and Dr. Janeway called attention to specimens of heart containing air, likewise exhibited by him at a previous meeting.

#### CANCER OF THE STOMACH WITH ABSENCE OF PAIN.

DR. E. C. SEGUIN presented a stomach removed from a patient whom he had seen in consultation with Dr. Thurman. The patient, aged 75 years, enjoyed good health until the summer of 1876, when she fell below par. She visited the Centennial, but went through it without a chair, thus showing a considerable amount of endurance for her years. After her return she suffered from dyspepsia, anorexia, and nausea. Dr. S. saw her Nov. 13th. The only symptoms she then complained of was great weakness and marked emaciation. Dr. Thurman discovered a painless swelling in the left hypochondrium, just below the border of the ribs. From the absence of all positive symptoms this tumor also discovered by Dr. Seguin, was thought by both gentlemen to be impacted feces. The swelling was manipulated and enemata given, and after a few days the mass seemed to disappear after the discharge of several scybalous masses. In the beginning of December the symptoms of dyspepsia became more marked. The first vomiting occurred only two weeks before death; was very slight in character. About this time there was regurgitation of food, mixed with a little brownish liquid. At no time was there any coffee-ground vomiting. The emaciation progressed, the repugnance to food was very great, and the loss of strength was extreme. Shortly after the disappearance of the tumor in the left hypochondrium, there was another tumor near the median line and on a level with the other tumor, which was duly recognized as an independent affair and as a cancerous growth. The specimen was chiefly interesting in connection with its clinical history. The specimen on examination was mainly composed of cylindrical epithelium.

DR. BRIDGON referred to a case of cancer of the stomach, in which there was no pain or vomiting, but in which the diagnosis was made from the progressive emaciation. He asked if absence from pain was uncommon.

DR. FLINT answered that the absence of marked pain was the rule.

DR. M. P. JACOBI remarked that, before arriving at a diagnosis of such cases by exclusion, two diseased

conditions should be taken into account, viz.: the prodromic stage of leukaemia, and progressive pernicious anemia.

DR. JANEWAY mentioned a case of cancer of the stomach, the diagnosis of which he made by discovering the umbilicated nodules of cancer of the liver. As primary cancer of the liver is rare, and as secondary disease follows cancer of the stomach, the presumption is legitimate that the latter condition of things exists. In addition to this evidence, when a tumor of the stomach exists, the diagnosis is quite positive.

In regard to vomiting as a symptom, much might be said. He believed that it was most frequently associated with deposits in the neighborhood of the pylorus. In that situation the peristaltic action of the stomach was seriously embarrassed. The contrary was the case with tumors in the line of the greater curvature—and hence, in those, absence of vomiting and pain was the rule.

#### DANGERS OF SIMON'S EXPLORATION—RUPTURE OF CYST OF SPLEEN.

DR. BRIDGON presented a specimen of spleen for the purpose of illustrating some of the dangers associated with Simon's method of exploring the rectum.

The following history was prepared by Dr. THOS. W. BUSCH, Acting Senior Assistant to House Surgeon: Mrs. E. B., *æt.* 36, was admitted to the Presbyterian Hospital July 14, 1877; is a native of Switzerland, has been a factory hand most of her life.

Patient gives no account of any disease during her childhood and early menstrual life, except a mild attack of rheumatism. At this time she also had frequent, almost daily, bleeding from the nose. Began to menstruate at sixteen; courses regular but very profuse. Was married at twenty-one; has had five children at intervals of about three years; no miscarriages. Was delivered of her last child three years and three months ago; nursed it a year and a half. Her courses appeared six weeks after this accouchement, have been regular to July of last year, from which time till the present they came every three weeks; she missed her last turn. During her last pregnancy patient had an attack of what appears to have been pneumonia, which threatened to cause an abortion.

From July of last year a harassing cough, unaccompanied by any expectoration, has troubled her. Its severity at length obliged her to take to bed. One day in the early part of last April patient ventured to get up and do some housework. While thus engaged she felt dizzy, lay down upon a bed, and became unconscious. She remained so, she thinks, about ten minutes; then, having partially regained her senses, she attempted to rise, and found that the right side of her body and face was paralyzed, though not completely, and that she had lost her speech. Sensation remained unimpaired. In a week she had recovered sufficiently to get up and move about.

Three months ago patient noticed a lump, scarcely as large as an egg, in her left side, about an inch above the centre of the crest of the ilium. Shortly before it appeared she experienced stitching pains at the place whenever she would assume certain constrained positions. For a month after patient became aware of its existence the tumor did not inconvenience her in the least; then it began slowly to increase in size and to give her some pain; her urine became very red and turbid, and has continued so since. On the 4th of July, patient, while stooping at work, felt severe pains about the tumor. From this time it has grown very rapidly, and has given her much more pain than usual.

Two or three weeks before admission patient was laid up with a painful swelling of the legs, which were covered with petechial spots. Her lower limbs have been similarly affected on several former occasions. Though patient has been living in a notoriously malarious region for years, she has not actually had chills and fever until just before entering the hospital.

Patient gives no history of disease of the heart nor of the lungs, nor does physical examination reveal anything abnormal. Examination of her urine indicates the existence of Bright's disease, which may account for the occasional pains in the back, with swelling under the eyes, which patient noticed ever since she came to America—eight years ago. There is no evidence of constitutional disease. It seems that patient has a marked disposition to hemorrhages in various forms.

On admission patient presents an emaciated and very anæmic condition. The right side of her face and body has not yet fully recovered from the paralysis. A slight swelling remains about her ankles, and bluish spots are still faintly visible on her legs.

A tumor the size of a new-born child's head is found in patient's abdomen, occupying completely the left iliac and lumbar regions. The lower portion of tumor has well defined limits; its upper portion is covered by the ribs. It is ovoid in shape, the smaller end, directed down and inwards, reaches the mesial plane in the hypogastric region. The tumor has an elastic feel, is distinctly nodular, slightly movable, somewhat tender, especially at its most prominent part, where it exhibits fluctuation. It is not connected with the uterus, which is perfectly mobile and of normal depth. Percussion over the tumor elicits a dull sound. This dullness may be traced up under the left ribs, and appears to be continuous with that of the spleen. Dullness is also heard at the back behind the colon. There is a small resonant space immediately above the posterior half of the crest of the ilium. With aspirator and fine needle about an ounce of fluid was withdrawn from the tumor for examination. It has a cloudy amber color, contains many small flocculi; on standing, an abundant whitish deposit soon falls; it is highly albuminous, of a sp. gr. 1020, reaction neutral. Under the microscope it showed a great abundance of very granular leucocytes, free nuclei, and a few red corpuscles. No mucus nor cholesteroline crystals, nor any of the constituents of urine, could be found.

A hasty examination of patient's blood showed the red and the white corpuscles to be in normal proportion. Patient's urine has a dark reddish color and is cloudy. She says it is not as dark and turbid as it has been. It contains albumen five per cent., large and small hyaline and granular casts, also epithelial casts.

July 25th. At a consultation held this afternoon to determine a question of diagnosis (patient being under ether), several gentlemen examined the tumor through the abdominal walls, after which Dr. Bridgdon introduced his left hand into the lower bowel, and after a thorough exploration expressed the opinion that the tumor was splenic.

July 28th. Patient passed a restless night. This morning she gave all the symptoms and signs of a general peritonitis. Ordered Magendie's Sol. Morph.  $\frac{ij}{x}$ , subcutaneously every two hours, brandy internally, and turpentine stupes on abdomen. At 12 M. patient in a state of collapse; died at 6.40 P.M.

Autopsy twenty hours after death. Body already in an advanced state of decomposition.

Heart apparently normal.

Pleuritic adhesions on right side; lungs otherwise apparently normal.

The omentum adherent to, but easily separated from, the anterior abdominal wall. Peritoneum coated with recent lymph. A loop of small intestine lay across the tumor and was bound down to it by fibrous bands, as was also the omentum. An abundance of yellowish gray fluid in the dependent parts of peritoneal cavity.

The tumor, as felt through the abdominal walls during life, consisted principally of the *spleen*, which, when removed from the body, had a long diameter of ten and a half and a transverse diameter of five inches, was of a dark greenish color, weighed twenty-three and a half ounces, emphysematous with gases, the result of decomposition. Near its upper end anteriorly is an irregularly circular depressed cicatrix. On the anterior surface also there is an opening formed by the rupture of peritoneum and adhesions, leading to an irregular collapsed cavity in the substance of the spleen.

*Liver* weighs four pounds.

Cortex of left kidney of normal thickness.

A more minute examination of the organs is not practical, because of the degree of post-mortem change.

Dr. BRIDGON was by no means certain whether the rupture was that of cyst or a hematoma. At the time of the autopsy the body was in such an advanced stage of decomposition that it was impossible to determine the point with positiveness. It was, however, supposed to be a liquefied infarction, an opinion which was shared by several of the members present. The greatest care was used in introducing the hand, and no accident would have occurred if the organ in question had been healthy.

#### CONGENITAL DISPLACEMENT OF VISCERA.

Dr. JANEWAY presented photographs from the autopsy of a subject of congenital displacement of the viscera. The patient was an inmate of Bellevue Hospital, and his condition was recognized during life. On auscultating the heart, its beat was feeble and distant. At first it was supposed that hydro-pneumothorax existed, and that the organ had been crowded to the right side. The diagnosis was soon cleared up on that point, when congenital displacement was made out. Examination of other organs was made, when a transposition of the liver and spleen was discovered. At the autopsy, which was made with some difficulty (on account of the widow, who was aware of the anomaly), a complete transposition of the internal organs was discovered, namely, that of the liver, heart, spleen, large intestines, caecum, sigmoid flexure, and arterial distribution. It was not ascertained whether or not the patient was left-handed.

#### DISTENTION AND RUPTURE OF BILE-DUCTS.—ABSCESS OF THE DIAPHRAGM.—PERITONITIS, ETC.

Dr. JANEWAY next recited a history of the post-mortem examination of the late Dr. John A. Brady, of Brooklyn. He made the autopsy in company with Drs. Flint and Hutchinson. The body was deeply jaundiced. On opening the peritoneum there were evidences of recent peritonitis, the intestines being agglutinated, and the cavity containing bile-stained serum. The transverse colon, pyloric extremity and duodenum were bound together against the undersurface of the liver. The latter organ was normal in size. The left pleural cavity contained fluid compressing the left lung. At the apex of this organ there was a small amount of fibrinous exudation. There was oedema of the right lung and congestion throughout, except along the anterior border. The lower lobe was also the seat of lobular pneumonia. The liver,

duodenum, pyloric extremity of the stomach and transverse colon, were removed in one mass. In detaching the liver, the left half of the diaphragm was found filled with pus. On opening the duodenum, the common duct was found to contain a large, thick, black and porous calculus about as large as a hickory nut, and behind it another of similar character. The common duct was normal in size, but the cystic and hepatic ducts were markedly dilated. In the gall-bladder, which was small and diminished in size, was a small calculus with facets bathed in a little bile of yellowish color. On tracing up the bile-ducts, they were found markedly dilated from obstruction, and in some places suppuration had taken place. At two different points in the neighborhood of the coronary ligament, the cellular tissue was infiltrated with bile. This latter condition was evidently due to the rupture of one of the distended ducts, inducing abscess of diaphragm, peritonitis, pleuritis, and pericarditis.

Dr. FLINT stated that fourteen years ago Dr. Brady had several attacks of hepatic colic, attended with the passage of several gall-stones. After this he was free for several years. Two or three years ago he complained of uncomfortable sensations, but there was no distinct attack until the week before he died. This passed off in the usual manner, and a second attack, a few days after, was followed by peritonitis, and death in forty-eight hours.

The Society then went into executive session.

## New Instruments.

### A NEW CATHETER-GAUGE.

By H. E. HANDERSON, M.D.

The accompanying cut represents (half size) a simple, convenient, and accurate "Catheter-Gauge," constructed on a somewhat novel principle. It consists of a metal plate perforated by a triangular opening 169.33 mm. (6.67 in.) in length, with a width at the base of 13.33 mm. (0.525 in.). This opening is graduated to both the French (Charrrière) and American (Van Buren) scales, while the reverse side of the plate contains the nearest approximation to the so-called English scale, with a comparative scale of English inches and French millimetres. The catheter, sound, etc., to be measured, is simply inserted in the base of the opening and slid towards the apex as far as it will go, when the parallel lines will at once indicate its size according to either scale. Those practitioners who devote much attention to urethral diseases, will, I think, find this gauge a useful and reliable instrument. It is manufactured by John Reynders & Co. of this city.

784 LEXINGTON AVENUE, Sept. 4, 1877.

ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from September 23 to September 29, 1877.*

WOODHULL, A. A., Major and Surgeon. When relieved from duty at Camp Halleck, Nev., to proceed without delay to Alcatraz Island, Cal., and report for duty at that post. S. O. 117, Div. Pacific and Dept. of California, Sept. 21, 1877.

MOSELEY, E. B., 1st Lieut. and Assistant Surgeon. Assigned to duty at Jackson Barracks, La. S. O. 147, Dept. of the Gulf, Sept. 20, 1877.

CRAMPTON, L. W., 1st Lieut. and Assistant Surgeon. Assigned to duty at Jackson Barracks, La. S. O. 146, Dept. of the Gulf, Sept. 19, 1877.

TAYLOR, M. E., 1st Lieut. and Assistant Surgeon. Reassigned to duty at Baton Rouge, La. S. O. 148, Dept. of the Gulf, Sept. 21, 1877.

OPENING OF THE UNIVERSITY OF PENNSYLVANIA MEDICAL SCHOOL.—The new régime at the University Medical School began on Monday, October 1st, at 12 M., with the introductory address delivered by Prof. Wm. Pepper, M.D. The changes instituted in the medical curriculum last spring take effect, it will be remembered, with the opening of the present session. The address was delivered in the University chapel, and was listened to by a large and attentive audience, consisting of the Board of Trustees of the University, the various faculties, a large number of city officers, members of the medical profession, and others. The address was upon the subject "The Higher Medical Education—The True Interest of the Public and Profession," and was exhaustive and masterly. Prof. Pepper only read selections from the oration, the whole of which, together with some interesting statistics, will be published in pamphlet form on or about November first.

The main argument of the address, written down in brief, would run somewhat as follows, viz.: The monotonous routine of medical education within the last fifty years, with no improvements and few new features adopted. The enormous material progress of our country compared with its backwardness in art, science, education, literature, and statesmanship, as seen at the Centennial Exposition last summer. The position of the medical profession in America far from satisfactory. The high moral tone of the best element of the profession contrasted with the fact, that of all professions it is the one in which the fewest members are able to earn an honest living. The question of reform. The objection to this reform, on

the ground that the present status of medical education is fully up to our present state of development, met by the showing of the requirements for a degree of the University of Pennsylvania Medical School in the year 1765. (This was the first medical school established in America.) *These requirements show that a far higher standard of medical education was demanded and in vogue then than we now possess, and that since that time the standard has been steadily going down.* Among other things, attendance upon clinics was obligatory from 1765 to 1845—since then it has been entirely voluntary. The University has been the parent of all American medical schools, and if she lowered her standard it was but natural that they should follow her example. Abroad, where the medical schools have kept abreast of progress in medical science, we notice five conditions not found in America (except at Harvard and the University of Michigan, and in future at the University of Pennsylvania), viz.: (1) Preliminary examinations; (2) terms of nine months each for four, five, or six years, and a regular gradation of studies; (3) partial examinations at intervals; (4) examination for a degree by an impartial, disinterested board; (5) careful personal, clinical, bedside training. In many countries the degree of B.M. only is given at the end of this period, and that of M.D. conferred after from three to five years' additional hospital study. The fact of a higher standard existent not only in the old and wealthy nations, but even in Brazil and Australia. The objection that the adoption of these reforms would produce a class of hyper-educated physicians, too absurd for confutation. Barbers serve a three-years' apprenticeship, carpenters are four years in learning their trade, and pilots seven. Nowadays it in reality only requires *ten months* (two terms of five months each) to learn the *practice of medicine!* Government cannot restrict the number of medical schools. Though protective in other matters, it has never attempted protection in medical education. In other countries there is about one medical school to every 3,000,000 or 5,000,000 of inhabitants. Here, with 45,000,000 of people, we have sixty-five regular medical schools. The fees at American medical schools have been lowered and the terms shortened to avoid being underbid in this unlimited competition. The supply of not only medical schools, but also of medical men, has run ahead of the demand. The three glaring evils of the present system are: (1) The enormous over-production of medical men. In the year 1875, 3,000 medical practitioners were qualified. In addition of this number, it has been calculated that 200 physicians emigrate annually to America. It requires from 1,500-2,000 persons to support a doctor. With a population of 45,000,000 in 1877, we have some 62,383 medical practitioners. This makes a proportion of one doctor to every 618 of the population. The immense difficulty of a living to the rank and file of the profession with this condition of affairs. (2) The lowering effects upon the moral tone of the profession of this state of things, and the increase of quacking and humbug. The frequent reports of the sale of "Bogus American Medical Diplomas" abroad. (3) The evil effects of the vastly increased and increasing number of medical dispensaries. It has been calculated that in London fully one-fourth of the population depend entirely upon gratuitous medical assistance. Of these a large number are entirely able to pay for the services of a physician. Evidently, the time is ripe for complete and unsparing reform.

The remedies proposed: (1) A higher diploma to be conferred after a post-graduate course of instruction. But here the answer is made us, that this new degree

also can be bought and sold. (2) The only real remedy then is and must be—action by the legislatures of the separate States. Canada, at present, has regular legislation in this matter, and there is no reason at all why our State legislatures should not appoint regular committees to take control of and supervise the system of medical education. This has been the burthen of commencement addresses for years past. Then, as to change in the requirements for a degree, while we are waiting for legislatures to set to work. Harvard made the change in 1871. Her plan was crowned with eminent success, and the superior quality of her medical graduates at once acknowledged. Lately, the University of Michigan has also made the change, and the Johns Hopkins School at Baltimore is to be built upon the same plan. The University of Pennsylvania also has fully made up her mind to take the step and intends to persevere in this straight path, no matter how small her classes become in consequence. In order that the degrees obtained at the University of Pennsylvania medical school may be recognized as the guarantee of their possessor's superior preparation, the words "*University of Pennsylvania*" are to be added to the statement of the degree of M.D.

The number of students forming this year's class at the University, contrary to all expectation, is but slightly, if at all, behind last year's matriculating class in numbers. In fact, from present appearances, it looks very much as if the American public, which, according to some of the enemies of the new system, would not appreciate physicians educated above the wants of the community, intended on the contrary to show its full appreciation of this new step in the right direction, by sending a larger number of its sons than usual to the University medical school, and so making the class this year larger than it was last.

**AMERICAN ACADEMY OF MEDICINE.**—An association of medical men and laymen with the above title has been formed, numbering thus far forty-three names. The object of the said organization is to advance the interests of scientific medicine with the public. The next meeting will be held at Easton, Penn., on the third Tuesday in September, 1878.

**NEW YORK SOCIETY FOR THE RELIEF OF WIDOWS AND CHILDREN OF MEDICAL MEN.**—At a quarterly meeting of the Board of Managers, held at the New York Academy of Medicine, on September 19, 1877, Surgeon George Peck, U. S. Navy, was unanimously elected a life member. Medical Inspector Peck had contributed one hundred and fifty dollars to the funds of the Society in June last, and was in that month elected a benefactor.

**INTRODUCTORY LECTURES.**—The introductory address to the winter course of lectures at the College of Physicians and Surgeons was delivered on Monday evening, October 1st, by Prof. John G. Curtis—subject: "Plant and Animal Life."

The introductory lecture of the regular course at the Medical Department of the University of the City of New York, was delivered on Tuesday, October 2d, at eight o'clock, P. M., by Prof. William H. Thomson.

The opening exercises of the winter session at the Bellevue Hospital Medical College took place on Wednesday evening, October 3d, at eight o'clock. The address was delivered by Prof. William M. Polk.

**NEW YORK VETERINARY COLLEGE.**—The reopening of the New York College of Veterinary Surgeons took place at their building, No. 205 Lexington Avenue, on the evening of October 1st, at eight o'clock. Addresses were delivered by Dr. Rawson, President of the Col-

lege, and by Profs. Going, Fairfield, Finlay, and Comstock.

**PROF. LEWIS A. SAYRE.**—We are happy to chronicle the safe return of this distinguished surgeon from his visit among the scientific men of the Old World.

**YELLOW FEVER.**—Reports from Augusta, Ga., dated October 1st, state that four deaths from this disease have occurred in Port Royal, S. C. Special dispatches from Jacksonville, Fla., and bearing the same date, bring the information that fifteen new cases had been seen that day in Fernandina, and that medical assistance had been asked for from there and from Charleston. The weather is unfavorable, and nearly one-sixth of the present population at Fernandina are sick with the fever. No new cases have been reported in this city.

**MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.**—At a stated meeting of this Society, held Sept. 24, 1877, it was voted to grant certificates of membership to Drs. D. F. King and R. A. Page.

**DR. J. H. POOLEY,** Prof. of Surgery in Starling Medical College, after having completed the course of lectures at Dartmouth College, interrupted by the sudden death of Prof. Crosby, has returned to Columbus, where he will deliver the surgical course during the coming winter.

**THE TUKE PRIZE.**—The W. and S. Tuke Prize (one hundred guineas) has been awarded to Dr. E. C. Spitzka, of this city, for the best essay on the Somatic Etiology of Insanity, by a committee of the Medico-Psychological Association of Great Britain.

**THE VISITING CORPS OF THE HEALTH BOARD.**—We have received the following letter from a member of the Visiting Corps of the Health Board, and gladly give it a place: "As I think a wrong impression will be given by your editorial in the Record of September 22d, in reference to the Visiting Corps of the Board of Health, it seems to me but right that you should explain that the average of 94 visits a day, referred to in Dr. James' report, does not mean that 94 cases of illness were visited in a day, but simply that the physician inquired at the rooms of 94 families whether there was any sickness there. In many families there were no children at all, and in the vast majority of others there either were none sick, or else the patients were already under medical care; so that the number actually prescribed for was comparatively small (about one in every 28 families). When you reflect that many of the tenement-houses contain twenty families apiece, it will be seen that 94 visits is not such a large number after all. This note is not intended for publication, but I trust that you will do the Board of Health Visitors justice in this matter."

**COMPARATIVE LONGEVITY.**—Official documents show that in Italy, for every million of inhabitants, there are 71,602 individuals who have attained the age of 60 years; in Great Britain there are 72,910; in Holland, 76,982; in Sweden, 78,187; in Denmark, 86,657; in Belgium, 88,432, and in France, 101,495. On the other hand, Great Britain has 15 centenarians for every million of inhabitants; France has 7.3; Belgium, 7; Sweden, 2.6, and Holland, 1.3.

**DEATH FROM CHEWING TOBACCO.**—A boy was recently admitted into the Melbourne Hospital, suffering from the effects of chewing tobacco. He was in a very weak state, and complained of severe headache and dysentery. He became gradually unconscious and partially paralyzed, and died on the following day. The cause of death was narcotic poisoning.

### LECTURES ON DISEASES OF THE HEART.

By AUSTIN FLINT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE, IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

[Reported for THE MEDICAL RECORD.]

#### LECTURE VI.

FUNCTIONAL DISORDERS OF THE HEART—REDUPLICATION OF HEART-SOUNDS—ALTERNATE STRONG AND WEAK SYSTOLE—INFREQUENCY OF THE HEART'S ACTION—INCREASED FREQUENCY OF THE HEART'S ACTION—INTERMITTENCY OF THE HEART'S ACTION.

GENTLEMEN:—I will next call your attention to the functional disorders of the heart; those disorders which do not involve inflammation, nor any appreciable lesion either of the valves or the walls of the organ. These functional disorders vary in character. They may coexist with organic lesion, yet having no mutual dependence upon each other. I will raise this question at the outset: How are we to determine that disorders of the heart are functional? The answer is this: we are to determine by the absence of physical signs of organic disease of the heart. We reach the diagnosis of functional disorders of the heart by exclusion; we exclude organic lesions. The different organic lesions, having, as they do have, diagnostic physical signs, the absence of those signs warrants the exclusion of the lesion. As a general statement, this is true. There are a few exceptions, but if with a proper degree of knowledge and self-confidence, and sufficiently careful examination, we find that there are no signs present of organic disease of the heart, we are justified in saying that the trouble, whatever may be its manifestations, is functional. We are able to say that the patient has no organic disease of the heart. If you have not already had the opportunity to make the observation, you will learn in the course of time how desirable it is to be able to make that statement to your patients, for with most of the functional disorders of the heart there is connected a great deal of anxiety and apprehension. Patients come to us for examination with the greatest trepidation; are reluctant to have an examination made, for fear that something wrong about the heart will be found. Perhaps there is no class of affections more terrible to the patient than diseases of the heart; nothing which strikes the mind with more terror than the idea of sudden death, so commonly associated with these affections. This common idea is fallacious, for the great majority of cases of organic disease of the heart do not terminate suddenly; but patients are not prepared to make any discrimination with regard to the different forms of organic disease of the heart. To say that they have disease of the heart is sufficient oftentimes to produce great terror, and that fact is to be considered. Suppose you find a lesion which is innocuous, as we do not infrequently; if we are obliged to say there is an organic affection, the statement should be coupled with such explanation as to remove the apprehensions naturally entertained by the patient. To impress more and more this negative method of reaching the conclusion that there exists only a functional disorder of the heart, let us suppose that here is our patient before us in a great state of anxiety and apprehension, and watching closely, as

they will do, while you are making your examination. He has stated his symptoms, you have examined the pulse, obtained the history of the case, and have perhaps in your own mind already reached nearly a positive conclusion in favor of its being a case of functional disturbance. But we cannot feel confident that no organic disease of the heart is present, unless that conclusion is based upon physical exploration and the absence of physical signs of organic disease. The physician, in order to produce the desired moral effect upon the patient, and relieve him from apprehension, must speak with a confidence which he cannot very well assume, unless it is based upon a conviction derived from physical exploration. We see the evils of this in practice. If the physician does not feel competent to reach a correct conclusion, he must resort to one of two things: either form a conclusion and take the risk of being in error, and do harm in that manner, perhaps by saying that the patient has an organic disease, when the truth is it is merely functional in character; or, on the other hand, call it functional when it is organic, and perhaps the patient dies suddenly; or, what is more commonly done, as we learn by experience to be reserved and non-committal, he does not give a positive opinion. Perhaps he says in this manner, "There is nothing of any great importance in your case," in a kind of indefinite way, and the effect is this: the patient thinks the physician believes he has disease of the heart, but does not wish to tell him. Patients rarely appreciate our ignorance, and that is the conclusion they draw from such non-committalism on the part of the physician, namely, that he knows, but does not choose to tell; whereas the truth is he does not know, and he answers indefinitely, because he knows that if he does otherwise, he runs a risk of committing an error in diagnosis.

Let us proceed with the examination of our patient. In the first place, we naturally direct attention to the size of the heart. Is it enlarged? To settle this question the apex-beat is found. Is it in its normal situation? Does an oblique line from it to the centre of the sternum form the hypothenuse of a triangle which outlines the superficial cardiac space? Is the area of cardiac dulness normal? We have now found that this patient's heart is not enlarged.

Next, with regard to valvular lesions, and we are satisfied, from the fact that there is no enlargement of the heart, that there is no immediate danger from those, for they give rise to danger by first producing enlargement of the heart and enlargement by dilatation.

But we wish to go farther. We have determined that the heart is not enlarged, and we will now determine whether there are present valvular lesions. We exclude lesions at the mitral orifice and those at the aortic orifice because we find no murmur, either systolic or diastolic. We will go one step farther and compare the aortic and pulmonic second sound, and we find that they bear a normal relation to each other. These conclusions may be reached with a very brief examination, but here let me give you a caution. Take sufficient time to make an examination which will be satisfactory to the patient and produce the desired moral effect. For your own satisfaction it may not be necessary to spend more than two minutes in making the examination; but to leave the impression upon the mind of the patient that your examination has been *thorough*, an impression that will greatly increase the value of your declaration that there is no organic disease of the heart present, it is well to consume perhaps ten minutes in the examination. That length of time will give you ample opportunity to

study the normal vesicular respiration at various places over the chest, and afford you an opportunity to familiarize yourself more thoroughly with the first and second sound of the heart, and all the relations which they sustain to each other. Having done this the patient will be very likely to have the impression that the examination has been thoroughly and completely made, and we can say to the patient that the heart is sound, and say it in such a manner as will convince him that he has a sound heart. There are no diseases, perhaps, in nosology where the signs are so constantly demonstrable as diseases of the heart, and perhaps no class of diseases which we are better warranted in excluding by the absence of those signs.

Let us now consider the different forms of functional disorder of the heart.

*First, we have REDUPLICATION OF THE HEART-SOUNDS.* This form possesses no great amount of practical importance, but it possesses interest, and we must be prepared to recognize it. By reduplication we mean one or both of the two sounds of the heart duplicated for each pulse; that is, four sounds, if both normal sounds are reduplicated; if only one sound is reduplicated we have three sounds. It is not common to find reduplication of both sounds.

It is exceedingly rare to find reduplication of the first sound without reduplication of the second, but it is tolerably common to find reduplication of the second without coexistent reduplication of the first sound of the heart.

The reduplication may be represented as follows: If the normal sounds are represented by the syllables lub-dup, the reduplication of the second sound will be represented by the syllables lub-dup-dnp.

We occasionally meet with cases in which both sounds are reduplicated, and in which such reduplication can be appreciated. How do we determine the reduplication? If we have four heart-sounds for each pulse, the interval of time between the heart-sounds is very small, and it is of particular interest to know how we are to distinguish this form from the next functional disorder to be considered. We are to determine the fact of reduplication in this manner; we compare the heart-sounds with the pulse; not the radial pulse, but the carotid pulse.

If the second sound is reduplicated, the rhythm is so peculiar that we can hardly mistake it. What is the explanation? The first explanation given was that the heart ventricles did not complete their contraction; that they stopped for an instant between the commencement and the end of the contraction, and then completed it. The most rational explanation, and that generally adopted, I believe, is this: We have in the reduplication of the heart-sounds a want of exact synchronism in the contraction of the two ventricles. Normally the ventricles contract together, but if one contracts a little before the other that fact accounts for the reduplication. Why is it, then, that we fail to have reduplication of the first sound in so great a proportion of cases, if that is the true explanation? If it is the correct explanation, we might naturally expect that both sounds would be reduplicated with equal frequency. The explanation is this: When reduplication of the heart-sounds is present, we have a feeble-acting heart; that is, the ventricular sounds are divided, and, of course, each is weakened. Now the first sound, so far as the valvular element is concerned, is a weaker sound than the second. When, therefore, the heart is weakened by this form of disorder, we do not get more than one of the elements of the first sound produced; we lose the first sound which is produced by the right ventricle, and the re-

duplication is not produced. But, under these circumstances, the second sound being louder and sharper in health, so far as the valvular element is concerned, we have an appreciable reduplication.

This form of functional disorder has more of scientific interest than practical importance. It occurs sometimes with valvular lesions, and sometimes in connection with healthy hearts. It sometimes continues for a few minutes only, and sometimes for hours and days; more frequently, however, it is transient. It is not attended by appreciable symptoms and does not claim any special treatment, and the reasons for its occurrence are not well understood.

#### ALTERNATE STRONG AND WEAK SYSTOLE.

The next form of functional disorder is likely to be confounded with reduplication.

We meet, occasionally, with a form of functional disorder of the heart in which every alternate systole is too weak to produce a radial pulse. The ventricular contraction is too feeble to produce a sufficient momentum of the arterial blood to cause a radial pulse to be appreciated with the finger. This occurs regularly, so that the pulse at the wrist represents only every alternate systolic ventricular contraction. It is very curious to notice with what regularity this irregular action of the heart is preserved, and it may continue for successive days.

Many years ago, before being acquainted with this form of functional disorder, I regarded it as a reduplication, and, moreover, observed and reported a case in which the interest rested chiefly in the fact that "reduplication of the heart-sound continued several days." As I was afterwards satisfied, this was a case not of reduplication, but of the form of disorder under present consideration.

There is a mode in which you may avoid this error, and that is, by making your observations in connection with the carotid pulse. This alternate weak systole is usually strong enough to produce a carotid pulse. This form of functional disorder may occur with valvular lesions, with enlargement of the heart, or it may occur without cardiac disease. The disorder has no special significance. Why it occurs we cannot explain. The patient may not be conscious of it. It claims no particular plan of treatment. It is more interesting as a clinical curiosity than as possessing any practical importance.

#### INFREQUENCY OF THE HEART'S ACTION.

Another form of functional disorder is infrequency of the heart's action. Not much attention has been given to this form of disorder, and, if I mistake not, my own knowledge of it has been acquired since the publication of the second edition of my work upon Diseases of the Heart.

The heart's action may be so reduced in frequency that we get a pulse numbering 50, 40, 30, and perhaps even less than that. I have met with a few such cases, and have reported them in a short paper which was read before the New York Academy of Medicine, and subsequently published in the "American Practitioner." In order to distinguish between this form of disorder and that in which we have alternate weak systoles, we have first to determine that the pulse corresponds in frequency with the heart's sound. If they accord, that is sufficient to exclude alternate strong and weak systoles.

If the pulse is diminished much in frequency, it is accompanied with certain nervous symptoms which do not correspond in all cases.

The patient is sensible of a certain feeling of dis-

comfort, and sometimes has a sense of impending death. In some cases there is a certain amount of mental aberration and a general feeling of prostration. Of course, in examining such a case, and before it is pronounced to be one of functional disorder, we must exclude organic disease of the heart as in all the different forms of functional disorder, by the absence of the signs of organic disease. This form of functional disorder does not tend to a fatal result; there is no danger accompanying it. In none of the cases in which I have observed it has a fatal termination occurred, but, on the other hand, all the patients have recovered from it after a short time.

It is not easy of explanation. It would seem that the retarded action of the heart is produced by some influence transmitted to the organ through the *par vagum*. In determining that we have this form of functional disorder, we must take into consideration the fact that the heart's action is rendered infrequent by cerebral disease, and by the influence of certain drugs. Of course, all these must be excluded before the conclusion is reached that the patient has this form of functional disorder of the heart.

The indications for treatment are to stimulate the patient by the use of alcohol, and perhaps counter-irritation.

This form of functional disorder is interesting, because of its infrequency, and it has scarcely been recognized as a form of functional disease of the heart.

#### INCREASED FREQUENCY OF THE HEART'S ACTION.

In the forms of functional disorder of the heart commonly met with, the action of the heart is increased in frequency without disturbance of the rhythm.

This disorder is illustrated in that very curious disease known as exophthalmic goitre, or Graves's disease, or Basedow's disease, in which we have a persistent frequency of the heart's action, 130 or 140 beats to the minute, and perhaps continuing so for years. We should naturally suppose that this, like other muscles, would become fatigued by such persistent rapid movement, but such is not the case. We meet occasionally with cases in which there is a rapid action of the heart persisting for days and weeks with regularity of rhythm, without the protrusion of the eyes and the enlargement of the thyroid body present in exophthalmic goitre. Still, these cases are comparatively infrequent. In the great majority of cases of functional disorder of the heart, characterized by increased frequency of the heart's action, we have with this rapidity a disturbance of the rhythm, or irregularity, and the disturbance occurs in paroxysms. These paroxysms are of variable duration. It may be for an instant only. The most common form is this: the patient is suddenly seized with a rapid and irregular action of the heart, and he is conscious of it, and painfully so—and it produces a fear, not infrequently, of sudden death. These paroxysms appear at different times with greater or less frequency, and in some instances the irregular action of the heart is excessive; the patient has an "insane heart," which may continue so for days, and sometimes for weeks. When it does continue so long, the consciousness of it is so painful and the apprehension so great, that we can hardly help feeling a great interest ourselves, lest there is something present more than functional disorder.

#### INTERMITTENCY OF THE HEART'S ACTION.

The form of functional disturbance which, perhaps, excites most apprehension is intermittency of the

heart's action. This is frequently associated with palpitation, as it is called. There is an exceedingly irregular action of the heart—"fluttering" is a term used by many patients to express it; sometimes a violent action, as though the heart was "struggling to get out of the chest, when suddenly there is an intermission in the heart's beat. The patient is conscious of this, and the suggestion to his mind is, "I am in danger of sudden death." Now, intermittency in the heart's action occurs in connection with valvular lesions and with enlargement of the heart. It occurs when the patient is not conscious respecting the presence of organic disease of the heart, and it is apt to occur in persons advanced in years without any coexisting evidence of organic disease. Intermittency in itself is never evidence of organic disease of the heart. It occurs often when the patient is not conscious of it; but the intermittency in this form of disorder is attended with the most vivid consciousness. Generally in the functional disorders of the heart in which the heart's action is increased, the heart-sounds are abnormally intense, especially the first sound. This is easily explained. I have had occasion to call your attention to the fact that when the ventricle acts, the curtains of the valves are already floated out so that they are actually in contact with each other. But when the heart is acting rapidly the ventricle contracts upon a small quantity of blood, and the consequence is that the valves are not thus floated out. We have, therefore, an intensified valvular element of the first sound; it is peculiarly sharp, loud, and valvular in some cases. Now, with regard to these forms of functional disorder of the heart, we are called upon to say to the patients, no matter how much disturbance there may be, or how great distress they may occasion, that there is absolutely no danger. We are warranted in saying that positively, and that mere statement is sometimes more important to the patient in way of curative influence than any remedies which can be employed. It is always important to say to the patients that they *must not* form the habit of feeling their pulse, and must keep themselves as far as possible from any knowledge whatever of their hearts.

How are we to treat these cases of functional disorder of the heart? We are to take into account the causation. Now, causation involves a natural conformation or natural constitution in some persons. There are some persons who have what we call irritable hearts, hearts easily excited into functional disturbance. To these persons we are obliged to say that very likely they will not be cured entirely. We may also say that we believe there is no danger, and that they will finally get over the disturbance to such an extent as to have but comparatively little of it. Aside from this innate predisposition, what are the causes? Tobacco is one; and, perhaps, when only moderately used. Functional disturbance of the heart occurs in connection with dyspepsia. It is said to do so from sympathy, but whatever may be the bond of sympathy, it is a clinical fact that the two conditions are very frequently associated. The condition of anemia favors functional disorders of the heart. Prolonged mental anxiety is a very frequent cause of these disorders; and excess in venery is also to be mentioned. When patients ask me concerning the cause of this disturbance about the heart, if it be functional, I usually enumerate the different causes and leave them to judge as to how far they are applicable in their own cases.

Of course, treatment involves removal of these causes. In cases of anemia the treatment involves the use of chalybeates, hygienic measures, and measures to improve the appetite and assimilation. In

those cases in which we find evidence of a naturally irritable heart we cannot say that cure is to be permanent, but we can promise the patients, with a good deal of satisfaction, that with the removal of all causes within control, and the use of certain measures for the relief of these, a certain degree of benefit will be sure to follow.

Finally, I wish to call your attention to the fact that we may have functional disorders coexisting with organic lesions, but not dependent upon them. The same causes which give rise to functional disorders of the heart in persons otherwise healthy, will operate in those who have organic disease of the heart, but in such cases the functional disturbance is more likely to be troublesome than when unassociated with organic lesions. How are we to determine the presence of functional disorder coexisting with organic disease of the heart? After a certain amount of practical observation it will not be difficult to answer this question. First, you will ascertain whether any of the causes of functional disorder are operating. Next, we can determine by physical signs whether the organic lesions which exist would be likely to occasion so much disturbance of the heart. We can determine that the organic lesions are not important. Now, suppose that symptoms of functional disturbance are present with little or no enlargement of the heart, or what enlargement is present is in the way of hypertrophy; we know very well, under these circumstances, that the lesions do not generally give rise to grave results. If, therefore, we find the phenomena present which have been described under the head of functional disorders, we have good ground for the conclusion that the disturbance complained of is functional, and if treated as such the patient is usually relieved. Functional disorder is especially present in patients with organic disease of the heart when they become anæmic. Let anæmia be developed by indigestion, by lactation, etc., and palpitation will be developed and become a troublesome symptom, and here we are to be careful that the disturbance is not imputed to the organic affection while it is due to that which gives rise to the functional disorder.

I wish to have you recognize this fact, that, in individual cases, we may have with organic lesions important functional disorders of the heart, and that we are to endeavor to avoid the error of attaching undue importance to the organic lesions from the fact of coexistent functional affection; for with the removal of the functional disturbance, the patient will suffer simply from the organic lesion, which may give rise to no symptom whatever.

### NON-SHORTENING OF THE CERVIX UTERI DURING UTERO- GESTATION.

BEING ABSTRACT OF REMARKS MADE BEFORE THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK, SEPTEMBER 24, 1877, ON A PAPER READ BY DR. P. BRYNBERG PORTER, ON "AN ANALYSIS OF THE EXAMINATION OF SEVENTY-SEVEN PREGNANT WOMEN, WITH A SYNOPSIS OF THEIR LABORS."

By ISAAC E. TAYLOR, M.D.  
OF NEW YORK.

MR. PRESIDENT AND GENTLEMEN:—The remarks which I shall make on this paper, just read by Dr. Porter, will relate chiefly to the condition of the cervix uteri during utero-gestation and after labor. So far as I am aware, the different views regarding the changes which occur in the neck of the uterus during pregnancy are four in number.

First, we have the view held by Leischmann, or what may be called the older doctrine, namely, that the cervix, during utero-gestation, is unfolded from above downward, and that, at the end of pregnancy, there is no cervix to be discerned.

Second, we have the view advanced by Stoltz in 1826, and accepted by Cazeaux in 1839, namely, that the neck of the uterus, during pregnancy, is obliterated from below upward. In 1840 I was a pupil of Cazeaux, and almost daily had the privilege of witnessing his demonstrations of this doctrine. The opinions of Stoltz and adopted by Cazeaux, I presented to the medical profession in 1842, when I edited Dr. Evory Kennedy's work on Obstetric Auscultation. I there gave drawings of the mechanism of the cervix uteri in the primiparæ and multiparæ, showing the difference from the older view entertained by the profession. They were the first given to the medical profession in America upon this subject, although subsequent to 1840 I had been teaching them to private classes studying the diseases of females.

Third, we have the view entertained by Litzmann, and presented in an article published in the *Edinburgh Journal* for April, 1877. This writer believes that shortening of the cervix takes place, but thinks he has demonstrated that in multiparæ the change is from below upward, while in primiparæ the process goes on from above downward. Of this view I will speak a little more fully hereafter.

The fourth is the view held by myself, namely, that no change whatever takes place in the cervix uteri from the time of conception to the time of labor, with the exception of physiological softening incident to pregnancy. So far as my observation has extended, I know of no authority which has recognized the position I have taken upon this question; and while the facts which have led me to the adoption of this doctrine are so plain and so easily demonstrated, and have been repeatedly demonstrated, not only to private pupils, but to large classes, both in Bellevue and in Charity hospitals, I am perfectly unwilling that they should pass away without recognition. I do not claim this recognition as an individual solely, but I do maintain that what has been done in this country in way of new investigations in this department should be credited to American obstetrics.

As early as 1851 I recognized that the teachings of my former preceptor upon this subject were at variance with the actual facts in the case; that his theory was no more correct than the older one; and that both brought us to the same conclusion, namely, that at the termination of pregnancy the cervix uteri is obliterated.

The views held by Stoltz and Cazeaux, as well as those advocated by Leischmann and Litzmann, have for their basis demonstrations made by touch only, while the doctrine which I present has its foundation on ocular demonstration and post-mortem examination.

In 1852 I began a series of investigations with reference to this question, and took measurements of the cervix while the woman was placed in various positions, such as standing, lying upon the back, and in the genu-pectoral position of the present time. In 1862 I read a paper before the New York Academy of Medicine, and published it in the June number of the *American Medical Times*, of this city, in which my views regarding non-shortening of the supra- and infra-vaginal portions of the cervix uteri, up to the complete termination of pregnancy and the first stage of labor, were stated under ten propositions. At that time I exhibited post-mortem specimens at full term, as well as diagrams illustrating my views.

From the investigations which I had made at various periods in pregnancy, at full term, in the first stage of labor, and from post-mortem examinations made upon the bodies of women who had died—without disease of the uterus—before, at the commencement of, and after labor, I reached the conclusion that the cervix uteri, during utero-gestation, does not undergo any shortening or effacement of the supra- and infra-vaginal portions, but retains its entire length, and in many cases is increased in length. It only becomes dilated at the commencement of labor, and serves simply as a channel between the body of the uterus and the vagina. This dilatation is accomplished through the combined operation of the softened condition of the neck and the pressure incident to the descent of the child's head: the pressure being caused by the contractions of the uterus, the dilatation first commencing at the internal os. When this expansion has been commenced, it slowly passes to the os externum, and the cervix, in that manner, is gradually unfolded to a limit sufficient to permit of the passage of the child's head, lengthened from one and a half to three inches. There is no more perfect and practical illustration of how this is effected than the gradual expansion of the anus of the horse during an evacuation, and the contraction which ensues after the evacuation has taken place.

The expansion of the cervical canal by the head of the child is not effected in the manner described by Matthews Duncan—the body of the uterus pulling upon the cervix and vagina very much as the arms pull on the leg of a boot while the foot is being pushed into and through it. We might as well say that the vagina or the perineum is pulled back as the child rides over it, while it is well known that it merely recedes and contracts as soon as the head is born.

In 1859, seventeen years after I edited Kennedy's work, Duncan, who speaks authoritatively upon this subject, published a paper in the *Edinburgh Medical Journal* for March, on the changes in the cervix uteri during pregnancy. In that paper he endeavors to dispel the errors which, as he claims, Stoltz had the credit of first assailing, and adopts, with some modification, the views entertained by Stoltz and Cazeaux. He argues that the older view has no status whatever, and that it is a delusion, and claims that the doctrine of Stoltz and Cazeaux is the only one which can be sustained by reliable demonstration. He illustrates his views with actual anatomical dissections (which are outlines of diagrams taken from Coste, Favre, Hunter, and one of his own at eight months), so as to make it imperative on obstetricians to accept them implicitly, or disprove them by other dissections carefully made.

In discussing the subject, Duncan says: "I intentionally omit the latter days of the ninth month of pregnancy, as silent and painless labor is often really going on." "I mean that contractions of the uterus, usually without pain, are effecting the complete obliteration of the cervical canal."

He is, therefore, a firm believer in the views of Cazeaux, my preceptor in 1840.

My article appeared in 1862, three years after Duncan had published his essay.

In 1863 Duncan published a second paper upon this subject, in which he says that modern investigations have no standing; that the views of Stoltz and Cazeaux are incorrect, and not modern, but that the credit of their discovery must be given to Weitbrecht, a Russian anatomist, who wrote in the year 1750. He refers, in this paper, to a dissection of the uterus of a

woman seven months in pregnancy. Duncan himself gives a representation of a morbid specimen at eight months. Neither of the gentlemen present any specimen illustrating the condition present at nine months or at the tenth month of pregnancy. Receding from his former endorsement of the views of Stoltz and Cazeaux, I do not perceive how he has proved that they are preceded by Weitbrecht's discovery or his own. If Duncan means to say, by these specimens, that there is no change in the cervix uteri during gestation, he fails utterly to do so. He should have a specimen at full term, inasmuch as the important question at the present day is, does the cervix uteri maintain its perfect integrity up to the completion of pregnancy, or does it become obliterated in the manner Duncan pretended when he endorsed the views of Stoltz and Cazeaux? That he still believes in the views of Stoltz and Cazeaux is evident, as he has stated in his paper published in 1873, in the *Edinburgh Medical Journal*, "that a process of silent and painless labor is going on for some hours or days before the supervention of active painful labor."

In the April number of the same journal for 1877, Angus McDonald, of Edinburgh, presents the views of Litzmann, and in connection with those he gives the description of a morbid specimen, presented to the Obstetrical Society, and removed from a patient who died suddenly at the commencement of labor, and in which no change in the cervix uteri was observed.

The views held by the Vienna school, as illustrated by drawings—which, by the courtesy of those who have been there, I have been permitted to examine, and the same illustrations are seen in Cazeaux—lead us to precisely the same conclusion—namely, that at the termination of pregnancy there is no cervix remaining.

It will readily be seen from this brief review, that the views which I entertain regarding changes affecting the cervix uteri during pregnancy are entirely at variance with all which have been published, and more generally accepted; but their correctness or incorrectness can be so easily demonstrated that I believe them to be worthy of consideration. Some of the German journals have accredited this doctrine to myself, and I have also learned that that view is taught by Depaul, of France.

The reports of post-mortems made by Duncan and others, and having a bearing on this subject, have been from single cases: one case at seven months, another at eight months, etc. I have been exceedingly fortunate through my own practice, and by favors from my friends, in seeing not less than twenty-five post-mortem examinations in cases in which death took place during the eighth and ninth months of pregnancy. Of these sixteen were at term, some were at the commencement of labor, and some were in the first stage of labor. In all the instances, however, whether at eight or nine months, it has been found that the cervix has remained of the same length from conception until labor. In some cases the cervix becomes lengthened, and such lengthening is not due solely to labor, but to an increase which takes place physiologically before labor commences.

Of these twenty-five cases, the cervix measured in 10 from 2 to 2½ inches; in 11 from ¼ to 2 inches; and in 4 from ¾ to 1 inch.

Neither Weitbrecht nor Duncan, who adhered to the Russian anatomist's views so tenaciously, has given any representation of the cervix at the end of pregnancy. Eight months is as far as Duncan has advanced, and Weitbrecht made one dissection of a uterus at seven months. How the behavior of the cervix uteri at full term can be inferred from observa-

tions made one or two months previous to labor, I am unable to understand. If we are merely to theorize regarding what occurs in the cervix during the latter months of pregnancy, then neither Weitbrecht nor Duncan has any claims as a discoverer.

Litzmann made his examinations with the finger, and he has reached the conclusion that the cervix becomes obliterated, not only in a different manner in the primiparæ and multiparæ, but that its complete disappearance occurs sooner in the former than in the latter, because of the greater tension present in the wall of the uterus. The gravity of the child is also recognized as an element in this process.

I now return to Litzmann's position. He entertains the same view as Stoltz and Cazeaux, as he holds that the cervix uteri retains its integrity until ten days or a fortnight before labor.

Out of 81 cases investigated from the 36th to the 40th week—

There were 35 primiparæ,  
 " 46 multiparæ.

The cervical canal was in the primiparæ, *as a general rule*, markedly shortened. It measured not over  $\frac{1}{2}$  to  $\frac{3}{8}$  inch: in 5 cases it measured from  $1\frac{1}{4}$  to  $1\frac{1}{2}$  inches.

In multiparæ the tendency was to greater closeness of the inner os than in primiparæ, while the external was wide open.

In primiparæ, 60 per cent. were shortened.  
 " multiparæ, 40 " "

Litzmann, therefore, seems to show that in primiparæ the older view of Baudelocque, Rhamsbotham, and Leischmann prevails, while in the multiparæ the views of Stoltz and Cazeaux are demonstrated.

But the mere touch is by no means sufficient to enable us to decide accurately what changes, if any, take place in the cervix during pregnancy, during labor, or after labor.

If the woman is placed in the genu-pectoral position, and a large cylindrical speculum introduced, it will be found that the length of the cervix can be measured with the greatest facility by means of a sound introduced when the head presents, with a ring attached to the sound, and pushed down to the os time.

Through the speculum also it can be seen whether any changes have affected the supra- or the infra-vaginal portions of the cervix. If a multiparous woman is examined during labor—the vagina usually being sufficiently capacious to admit a speculum three or three and a half inches in diameter—a full view can be obtained regarding the appearance of the cervix before, during, and after the occurrence of a labor-pain. It will be seen that during a labor-pain the cervix becomes entirely obliterated, and as the head recedes after the cessation of the pain, the neck of the uterus will present the same appearance as if no labor was taking place. These then are the views which I entertain regarding the question of changes which occur in the cervix uteri during utero-gestation—namely, that there is no change whatever in the neck of the uterus from the time of conception up to the close of pregnancy, except softening, which varies very greatly in degree in different cases.

If there is ascent of the uterus with an anteflexed condition of the body, then there will be a lengthening of the intermediate part of the cervix; that portion which is situated between the body of the uterus and its cervix. In certain cases which fell under my observation at Charity Hospital, the impregnated uterus at three or four months measured from ten to twelve inches. I felt quite positive that my sound did not pass through the tissue of the organ, nor into the

Fallopian tube, and there was nothing by which we could say that pregnancy existed. Yet pregnancy was present, and after labor had occurred the uterus measured only three and a half inches.

How was so much lengthening to be accounted for? It was not in the gland nor in the cervix, but was consequent upon a physiological softening, and the ductility of the supra-vaginal portion, or that portion of the organ which is between the body and cervix.

If there is descent of the head into the cavity when there is amplitude of the pelvis, there will be shortening of the cervix consequent upon the weight of the child, and eversion will in this case be manifest, but more especially in multiparæ than in primiparæ; it will occur, however, in some cases in the primiparæ. The eversion will not then be recognized by touch; by which it will be supposed that the cervix is shortened. But when the patient is placed in the genu-pectoral position, and the speculum introduced, the eversion will be restored, and the cervix will be seen presenting its natural appearance; that is, with the physiological blueness incident to pregnancy. We are not to be unmindful that the cervix proper will measure longer in some than in others, varying from three-fourths to one and a half inch.

Now, all the views mentioned admit that the cervix uteri continues to have its full length up to within ten days or two weeks of the termination of pregnancy, and those who hold to views differing with my own admit that the cervical canal is not *obliterated until that time*. Angus McDonald, in the article already referred to, appears to entertain the idea "that there is no foundation, so far as the anatomical evidence furnished by the specimen before us extends to show, for the widespread delusion that the cervix uteri is used up during the latter months of pregnancy in the development of the lower segment of the uterus."

Whether the cervix is developed into the body of the uterus now rests mainly on the question, what changes, if any, occur affecting it within the *last two weeks* of pregnancy. Angus McDonald's case is really the only one in which post-mortem was made at the end of pregnancy or in labor, so far as I can ascertain. Duncan's cases amounts to nothing as evidence upon this point, because they were only at seven and eight months. Stoltz and Cazeaux went farther than Duncan, and admitted that the cervix was not shortened at eight and a half months; and this view Duncan still entertains, although he gives the credit to Weitbrecht as its discoverer. From the investigations made by different methods—by the touch; by the use of the speculum and measurement of the cervix by means of an instrument; with the woman on her back, or in the lateral, upright, and genu-pectoral positions, and applied in over 3,000 cases since 1840, in 2,520 since 1851, as well as from twenty-five post mortem examinations—I hold that no change occurs in the cervix uteri during gestation. It is the same cervix in its complete integrity as to length, at the close of pregnancy, as it was at the time of conception; but it becomes modified by a physiological change in its structure preparatory to the mechanism of labor, and it is only at labor that it undergoes the expansion and lengthening commensurate with the size of the head of the child. The head of the child is driven through that channel in the same manner that it rides over the perineum, the perineum immediately receding as it passes. Or, more correctly and clearly demonstrated, as can be noticed in the anus of the horse when he dung, the cervix uteri recedes in like manner and becomes closed, although not so firm as before labor.

## Original Communications.

CROUPOUS LARYNGITIS AND DIPH-  
THERITIC LARYNGITIS.

By J. LEWIS SMITH, M.D.,

NEW YORK.

PROF. STEINER, of the Francis Joseph Hospital of Prague, writes: "The attempt to distinguish croup and diphtheria as two entirely distinct diseases has been unsuccessful, both from an anatomical and from a clinical standpoint; indeed, there are many good reasons for supposing that these two affections are only varieties and modifications of one and the same process, which, in consequence of special influences and collateral causes as yet imperfectly understood, makes its appearance at one time as croup, at another as diphtheria." (Art. Croup, in "Ziemssen's Encycl.") Since many physicians appear to hold the same belief with Steiner, and others express doubt as to the relationship of the above affections, I shall briefly state certain facts, which, in my opinion, substantiate the following proposition:

*Croupous laryngitis and diphtheritic laryngitis, however closely their anatomical characters may approximate each other in certain cases, are totally distinct maladies.*

*First.*—Their duality appears from a difference in their causes—inflammations of the respiratory apparatus, whatever the exact part affected, ordinarily result from the same cause. This cause is somewhat vaguely expressed by the term "taking cold." Croupous laryngitis is not an exception to the rule. It occurs most frequently in the cold and changeable months, and in children who are most exposed to cool winds and changeable temperature. Thus Steiner, speaking of this disease, says: "It has been found to be most prevalent during moist, cold, changeable weather," and he agrees with Hirsch that it "prevails especially in a moist, cold climate, in narrow valleys, swept by cutting winds, on plains exposed to cold winds, and in localities where the temperatures are low, or violent changes occur." There are probably predisposing causes of croup in many instances, existing in the individual, but observations fully justify the belief that the exciting cause is as stated above. The cause of diphtheritic laryngitis is quite different, namely, a *materia morbi*, which operates independently of thermal changes in the atmosphere. The condition required is the presence and reception into the system of the diphtheritic poison. Hence, the number of cases of diphtheritic laryngitis is in proportion to the prevalence of diphtheria, and if diphtheria is epidemic during the months of mild and agreeable temperature, and absent during the months of cold and changeable temperature, this inflammation occurs only in the former period. Thermal atmospheric changes can only be a cause of diphtheritic laryngitis in this way, that diphtheria occurring in an individual is more apt to produce the characteristic inflammation upon those mucous surfaces which are already the seat of catarrh, than upon such surfaces as are in the normal state; and cold and changeable weather is the common cause of catarrhs.

*Second.*—Croupous laryngitis occurs upon all parts of the earth's surface, though it is said to be more common in high latitudes than in tropical regions, as we would suppose from the nature of its cause. On the other hand, diphtheritic laryngitis obviously oc-

curs only in those localities where diphtheria prevails. There are many towns in the United States in which diphtheria has not yet occurred, and of course diphtheritic laryngitis has not; but physicians in these localities meet from time to time isolated cases of obstructive laryngitis occurring in children, which show upon the fauces spots or patches of pellicular exudation, and a considerable proportion of which prove fatal, and which it is impossible to regard as anything else but true croup. Thus, an intelligent physician, having had a large practice of twenty years in Central New York (Onondaga county), has recently informed me that he has met, in the average, perhaps three such cases in the year, while the towns in which his practice lies have not yet been visited by diphtheria.

*Third.*—There are the supposed anatomical differences, which pathologists of world-wide renown have insisted on—namely, that the croupous pellicle lies upon the surface of the larynx, and does not penetrate it, while the diphtheritic exudation penetrates the mucous membrane of the larynx. I am not prepared to state to what extent this distinction holds true as regards croup, but I know that the diphtheritic pellicle does penetrate the mucous membrane of the larynx, while it lies upon, but does not penetrate that of the trachea and bronchial tubes.

*Fourth.*—The highest authorities in pathological histology, as Rokitansky, state that croupous inflammation may occur upon all the mucous surfaces, but that it is more common in the respiratory tract than elsewhere. And it is to be observed that Rokitansky made this remark after observing 30,000 dissections in Vienna, where diphtheria had not yet appeared. Now it seems to me unreasonable to deny this statement, and to regard those isolated cases which have long been known under the name croup, and which occur in localities that have not yet been visited by epidemics of diphtheria, as a form of diphtheritic inflammation, when we admit that an inflammation, occurring farther down the respiratory tract, and which appears to have similar anatomical characters, is croupous and not diphtheritic. I refer to croupous bronchitis and croupous pneumonia.

*Fifth.*—Croupous laryngitis is neither epidemic nor contagious. The present senior physicians of New York, the earlier part of whose practice extended over a period when there was no diphtheria in this city, and physicians in those interior towns in which diphtheria has not yet occurred, bear uniform or nearly uniform testimony to this fact, as I have ascertained by inquiry. On the other hand, diphtheritic laryngitis, as every one knows, is simply one manifestation of an epidemic and highly contagious malady. During the last two and a half years I was enabled to collect the records of twenty-six cases of membranous laryngitis occurring in family practice. Most of these cases were in my own practice, but a few of them I saw in consultation, and as they occurred during the period when there was a severe and protracted epidemic of diphtheria, they were doubtless mainly, if not entirely diphtheritic. In twelve, at least, of them, the evidence of contagiousness was clear and positive, from the occurrence of diphtheria in children who associated with them. Of the remaining fourteen cases, a few were seen only once or twice in consultation, and whether the diphtheria extended to others I did not therefore learn; in a few instances those affected with the laryngitis were the only children in the families, while in the remaining small number it seemed probable that the disease was produced by local insanitary causes, and it did not extend to others, so far as known. There may have been cases of croupous lar-

nginitis included in these last, but probably not more than one or two, if any.

The above facts seem to me to establish the duality of croupous laryngitis and diphtheritic laryngitis, as firmly as most other doctrines in medicine.

### CLINICAL NOTES OF CASES OF NEURALGIA IN CONNECTION WITH TROUBLES OF THE ACCOMMODATION OF THE EYE.

By GEO. T. STEVENS, M.D.,

ALBANY, N. Y.

It is my purpose to present a few typical cases of neuralgia as associated with troubles of accommodation of the eye, from a clinical point of view. I may premise that the cases included in this report are all those of habitual neuralgia, which had, at the time of examination, been of very considerable duration—generally many years—the paroxysms occurring from three or four times a year to once in a week or two. They were all cases of well-marked neuralgic character, and have been distinguished by the sudden accession of the paroxysms, the intensity of the pain, and its localization with respect to the distribution of particular nerves.

Neither of the cases reported has been of slight importance, but in every instance the patient has been unfitted for the ordinary duties of life, and usually forced to take to his or her bed during the continuance of the paroxysms.

In some of the cases, while there is evidence of a family tendency to neurotic troubles, no opportunity has been afforded for extending the observations much beyond the individual cases reported. In the others of the series the family tendency is well-marked, and treatment has been extended to a sufficient number to render it highly probable that in these families the neurotic tendency depends upon the form of the eye.

Delia H., aged about 21, consulted me February 14, 1876, on account of an attack of trifacial neuralgia of great intensity, and which at the time of her application to me had continued, with only slight remissions, for three months. She declared that she did not believe that she had been free from pain while awake during that time, and she had been able to obtain but little sleep. By the advice of friends she had concluded to submit to the extraction of her teeth, although they were all sound, in the hope of obtaining relief; but a more conservative friend induced her to consult me before the sacrifice was made. She informed me that she had been a sufferer from neuralgia as long as she could remember anything; that at times she would scarcely more than recover from one attack before another would supervene. The pain was usually in the region supplied by the trifacial nerve, sometimes on one side and sometimes on the other, but usually confined to the right side. The skin was extremely sensitive, and even the pressure of a comb in her hair was at times intolerable.

She informed me that her mother, like herself, had been for many years a sufferer from intense neuralgia.

She had never until quite recently experienced any trouble with her eyes, but now found that she could not see well at evening. She had never had pain in the eyes.

I found that she could only read Snellen 200 at 20 feet with either eye without the assistance of a glass, but that with cylinder + 15 axis vertical she could read Snellen 100 at same distance. In other words,

sight was increased two-fold. She was supplied with cylindrical glasses as indicated, which she wore and soon began to improve.

February 14, 1877, one year after the first interview, she called upon me to report her condition. She had rapidly recovered from the attack above described, and had not during the year suffered another. She had never known a similar freedom from attacks since her earliest recollections, and did not believe that since childhood she had before known a period of two months to pass without a severe attack. Her general health has also greatly improved since she has worn her glasses.

Mrs. B., aged 40, consulted me in September, 1876, on account of a suppurative inflammation of the lachrymal sac. While affording such surgical relief as the case demanded, I learned the following history: For twelve years she had suffered greatly from headaches, which were for the most part located through the temples. These occurred every two or three weeks, and sometimes more frequently, each attack lasting from one to four days, during which she was invariably forced to spend the most of her time in bed. The frequency and severity of the attacks steadily increased, until three years ago they assumed a decidedly neuralgic character. The pains were at times in the course of the distribution of the trigemini, and at other times in the arm, extending from the shoulder down the outer and posterior portion to the elbow. Some of the most severe paroxysms occurred under the lower point of the right shoulder-blade—a point which at the time of examination was extremely sensitive. So severe and continuous were these pains that during the winter next preceding her visits to me, and the one previous to that, she had been constantly under the immediate care of her family physician. Although less a martyr to her neuralgia in summer than in winter, she was rarely free from it.

Her daughter, aged 14, has been a victim of severe and habitual headaches, especially severe after work at school. Confusion of sight and intense pain through the head have been the ordinary result of reading even for a few minutes.

I found Mrs. B. to have an astigmatism corrected by a + 42 cylinder, which she procured and wore. The relief to her head was almost immediate, and the pains in the shoulders, back of neck, and under shoulder-blades quickly disappeared. She has now used her glasses eleven months, during which time she has not suffered from her old complaint, has been entirely free from neuralgia, except a few days of intercostal pain, summer and winter. If her glasses are laid aside for two or three hours during the day she experiences some headache, which, however, vanishes when the glasses are restored to duty. The daughter above mentioned has also found relief from her headaches by the use of correcting glasses.

The following history well illustrates the influence of the ciliary nerves in a case of acute neuralgia.

James McE., aged 28, consulted me April 26, 1877, while suffering from intense supra-orbital neuralgia. The eyelids somewhat red and swollen, the tears streaming down his face, and the fiery mark of a large mustard plaster on the forehead above the eye, all served to make up a picture of suffering rarely to be met with. He informed me that nine years previously he had suffered the amputation of an arm, the result of an injury, and that during his recovery from the amputation he became greatly exhausted. While in this exhausted condition he suffered his first attack of neuralgia. Since then he has had two or more such attacks annually, each lasting from four to six weeks,

except in a single instance, in which the attack yielded in two weeks.

The pain occupies the region of distribution of the supra-orbital nerve. It leaves him if he can get asleep, but returns the moment he awakes. During the period of the attack he is absolutely unfitted for work, and is generally confined to his bed day and night until it passes over. Has submitted to a variety of treatments, but has experienced little relief from any.

He has strabismus, the right eye having a decided east. Sight of that eye,  $\frac{5}{20}$ . Sight of left,  $\frac{30}{20}$ . In left eye there is a manifest hypermetropia of  $\frac{1}{30}$ . [Afterwards found total hypermetropia  $\frac{1}{4}$ .]

My first impulse was to inject morphia beneath the skin of the painful part; my second, to relieve the ciliary muscle of its tension. I accordingly dropped a few drops of solution of atropia into the left eye, and directed him to call again in two hours. He did so; the pain had entirely subsided, and did not return. Nearly two months later, however, he presented himself with a new attack. The first application of the atropia only partially relieved him, but the pain yielded to a second application made the following morning.

Mrs. M. H., aged 44, was for ten years a sufferer from neuralgia, with extreme nervous irritability and mental depression. The neuralgic pains, which were for the most part located in the vicinity of the seventh cervical vertebra, extending upward towards the hair, and at times towards and into the shoulders or down the back, were of a burning, continuous, and extremely violent character. Accompanying these pains was an habitual cutaneous anæsthesia of the hands and arms.

Under the influence of continuous pain her general health failed, and she became a confirmed invalid. Counter-irritation by means of fly-blisters, mustard-plasters of various kinds, and stimulating embrocations, were freely resorted to, tonic and narcotic remedies were persistently used, and the galvanic battery was employed for a considerable length of time. With these, the benefits of travel, of diversion of mind, and such other appropriate regimen as her physicians suggested, were faithfully tried. None of these remedies were productive of more than very slight temporary relief.

I saw her in November, 1876, and found hypermetropia  $\frac{1}{4}$ , for which glasses were prescribed.

About six weeks later she wrote me an enthusiastic letter describing the great improvement in her health, which she ascribed to the use of her glasses, and expressing her surprise that any such result should follow a relief to her eyes. "I only knew," she said, "that the origin of my difficulties was not in my spine, for no local applications benefited me, but rather made me worse. The difference in the condition of my nerves, then and now, is just wonderful." I have recently received another letter from this lady, in which she informs me that still, after nine months, the relief continues.

Mrs. A. was first seen by me May 19, 1876. She was thirty-five years of age, and married. During early life she had chorea, which, with varying severity, lasted from the age of fourteen until she was seventeen. For several years after her recovery from chorea she was a sufferer from headache, and during the last four years from intense neuralgia alternating between the trifacial nerves and the nerves distributed to the back of the neck, shoulder, and lower part of shoulder-blade. She has known little freedom from pain in waking hours for several years, but the paroxysms

occur with great intensity about once a month. Her father has been subject to sick headaches for more than thirty years, and her brother, who is a physician, is subject to frequent neuralgic attacks. She has a son aged fourteen, who suffers greatly from sick headaches.

Mrs. A. has compound hypermetropic astigmatism in each eye. She did not procure glasses for the correction of this evil until November last. Then her neuralgic troubles rapidly vanished, and in a few weeks she declared herself cured. She has enjoyed up to this time almost complete immunity from the affection which gave her so much trouble for many years, and speaks in terms of greatest enthusiasm to friends of her unexpected cure.

Dr. M., brother of this lady, has been subject to repeated attacks of supra-orbital neuralgia. He has in right eye hypermetropic astigmatism, while the left eye is normal in its refraction. He commenced the use of a cylinder for the right eye in November last, since which time he has enjoyed a freedom from neuralgia such as he has not enjoyed before in ten years past.

Mrs. C. E. A. visited me in company with her son Ned, who had poor sight and pain after reading, and who had hypermetropia. In course of conversation with the mother I learned the following particulars respecting herself.

Since childhood she had been a victim of neuralgia. In early school-days she had often been forced to leave school and seek her bed on account of severe attacks, and the neuralgic habit had continued with her up to this time.

Attacks, of late, had been most frequently brought on by fatigue or exhaustion from active mental or physical exertion. They had usually commenced with a feeling of great depression and weariness, to which succeeded intense pain, often located at the lower point of the right shoulder-blade, but of late more frequently over the left eye. The pain, sometimes accompanied by nausea, had in these attacks been of great intensity, and had in almost every instance forced her to keep her room and her bed for three or four days together, during which time the admission of light or noise to the apartment was a source of torture.

The paroxysms had occurred about once a month, though not at stated intervals.

Mrs. A. is a lady of much more than ordinary mental and physical activity. Her son Ned, as before stated, is hypermetropic, and she has another son, eighteen years of age, who is subject to sick headaches. Her mother and her grandmother suffered greatly from nervous troubles.

Mrs. A. had never had trouble from her eyes, and her attention was drawn to them as a source of her difficulty during this conversation. I found, after using atropia, hypermetropia  $\frac{1}{10}$ , and prescribed glasses of 42 inches focus, encouraging her to use them in the hope of obtaining relief from her neuralgia.

Five months after this Mrs. A. called to express her delight at the success of her experiment. She had worn her glasses habitually since I had seen her before, and had not experienced a single attack of neuralgia. Better than all, she had scarcely known the sense of exhaustion and depression which she had formerly experienced at the close of every day. From this, which had been of daily occurrence, she had been entirely free, except that it had occurred about once a month in the place of the former neuralgic attack.

The following case, which is of much interest in this connection, I transcribe from the selections of a

late number of *Annales d'Oculistique* (Mars-Avril, 1877).

Ragazzoni, Surgeon-in-chief of the Hospital of Bergamo (Italy), reports the following: *Acute glaucoma with sciatica—Iridectomy—Cure of the two affections.*

The case was that of a woman aged forty-four years, who had been amaurotic in the left eye during two years, the result of acute glaucoma. In the right eye she now had all the symptoms of inflammatory glaucoma, in addition to which there occurred about the same time with the glaucoma, an intense sciatica of the same side. There were well marked alternations of the ciliary pains and of those of the thigh.

No sooner had iridectomy been practised than the sciatica ceased as if by enchantment. The eye healed with the restoration of satisfactory vision.

"The coincidence of the cure of the sciatica and of the glaucoma," remarks the *Annales d'Oculistique*, "is a singular circumstance, and one inexplicable to the author."

Upon the theory that I have advanced elsewhere,\* that neuralgia even of distant nerves is very frequently dependent upon ciliary irritation, the coincidence so mysterious to the author is readily explainable.

The few cases which I have reported from my own practice are but fair illustrations of a very considerable number which I have observed during the last two years.

From very careful notes of many cases, I believe that I am fully sustained in drawing the following conclusions:

1. That among the centripetal influences which generate neuralgia, the irritability arising from a perplexity or exhaustion of nerves engaged in the function of accommodation of the eye must be regarded as by far the most frequent and important.

2. That where a family tendency to neurotic affections, including neuralgia, is found, we may generally conclude that the inherited tendency is transmitted in the form of the eye.

And 3. That many inveterate cases of chronic neuralgia, not amenable to other forms of treatment, readily yield to the simple process of relieving the eye from irritation resulting from difficult accommodation.

## Progress of Medical Science.

CASE OF OVARIAN TUMOR IN A CHILD.—Prof. McGraw, of Detroit, reports a case of ovarian tumor in a child twelve years of age. The enlargement of the abdomen was first noticed in May, 1876, and it rapidly increased. The patient had no pain except from distention, but had a constant diarrhoea and was short of breath. In August, 1876, the abdomen measured thirty-four inches in circumference at the navel. There was universal abdominal fluctuation, and no tumor could be made out by palpation. The patient was tapped and three gallons of bloody serum were withdrawn. Microscopical examination of the fluid revealed blood-globules, but no granular corpuscles. After tapping, the dullness on percussion became limited to the lower and central part of the abdomen, but no tumor could be mapped out by palpation. The fluid rapidly reaccumulated, and in four weeks' time the child measured thirty-six inches around the navel. On Sept 12th, the abdomen was opened and the fluid

found to be largely ascitic. The tumor, which was as large as the head of a new-born child, was found lying on the vertebra. When grasped, the bloody serum which it contained spouted out of the hole previously made by the trocar. The tumor consisted of a very thin sac containing a bloody fluid. The pedicle was secured by a clamp. The patient made a good recovery without a single drawback, and is now entirely well.—*Toledo Med. and Surg. Jour.*, July, 1877.

EXSECTION OF HIP-JOINT FOLLOWED BY AMPUTATION OF THIGH.—This case is reported by Dr. Murbach, of Ohio. The patient, a boy, twelve years of age, had suffered for a year and a half from morbus coxarius. Several abscesses had formed, and left discharging sinuses, and it finally became evident that the patient could not support much longer the constant drain on his system. On May 4th, the operation of exsection was performed, the head and upper half of the shaft of the femur being removed. The femur was found to be diseased in its entire length, but the failing strength of the patient rendered it necessary to postpone further operative measures. After the operation the patient did well, the pulse and temperature gradually becoming normal, and the wound closing rapidly until May 30th, when he became feverish and had pain in the knee and along the course of the remaining portion of the femur. On June 2d, the limb was amputated above the bifurcation of the femoral, by the circular method, and the wound closed simply by a couple of strips of muslin brought over the stump and secured by a bandage. The patient recovered rapidly after the operation. On June 15th he got up and walked across the room on crutches, and on June 29th the stump had entirely healed up.—*Detroit Medical Journal*, September.

STRUCTURE OF THE HUMAN PERITONEUM DIAPHRAGMATICUM.—According to Bizzozero, the limitations of the diaphragmatic peritoneum is in some places unbroken, and does not present any openings, while in other places it is pierced with round or oval openings, that are partly grouped together in islands, partly scattered about irregularly. The islands are of different shape and size, and are composed of from ten to sixty openings, varying from four to sixteen-thousandths of a millimetre in diameter. This arrangement of the limitans is intimately connected with the distribution of the lymph-canals of the diaphragmatic peritoneum. The lumina of the superficial vessels, instead of being everywhere separated from the peritoneal cavity by an unbroken connective-tissue layer, are separated from it over extensive spaces only by a connective tissue network. Over this network the limitans is stretched in such a way that the openings in the latter, as a rule, exactly correspond to the meshes of the former. In this way, if we put the endothelial lining out of the question, an open communication is established between the lumina of the lymph-canals and the peritoneal cavity. This anatomical arrangement is most developed, not in that part of the peritoneum which covers the centrum tendineum, but in that part which covers the muscles immediately surrounding the centrum. The lymphatic network is not, it is true, so close-meshed in this situation as in the centrum tendineum, but the individual vessels are much wider, so that even with the naked eye the membrane can be seen to be reticulated. These lymph-vessels are really lymph-pools, which are covered towards the peritoneal cavity by the already mentioned connective-tissue network and the cribose limitans.—*Centralblatt für die Med. Wissen.*, August 11th.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, October 13, 1877.

## THE HIGHER MEDICAL CULTURE.

IN a recent issue of the *World*, a medical gentleman of this city ventures to speak in favor of higher medical culture. We do not pretend to question his motives in so doing, but, on the part of the profession which he represents, we regret the act. With the most laudable intention of expressing the views of his brethren, he has persuaded himself to assume too heavy a responsibility. While he has our sympathy in failing to support his line of argument, if indeed any such is attempted, we cannot help wishing that he had never considered it his duty to write the letter in question at all.

As far as we can understand the writer, we believe he intends to advocate higher culture. No one objects to this, but his manner of putting it is somewhat peculiar, and leaves us in doubt as to whether he really understands his subject or not. We admit that the question of higher medical education is a great problem, and as such some little struggling is required to overcome it, but there is very little progress made when the problem has always the upper hand. For the sake of fair play, if for nothing else, we should like to see the parties in the contest a little more evenly matched. For the amusement and edification of a discriminating and impartial public, this is sometimes quite essential. We do not believe any one doubts that there should be a higher medical culture, and if we understand the writer correctly, he does not pretend to prove the contrary, but we have a lurking suspicion that he has some vague objection to new methods. The following paragraphs will no doubt clear up any doubts on this point in the minds of our readers, that the real way to succeed in medicine, as in any other "line of human effort," is "native intelligence coupled with untiring industry" (vide Smiles' "Self-Help"). Great men, it is true, get on without training, are perhaps born geniuses, but what are we to do with the large majority of young men who are anxious to study medi-

cine? These are the very ones who are least apt to "supplement all deficiencies by ingenious contrivances and more penetrating application," but to follow their leader and swear by their professor. The colleges, far from being an advantage to these men, are considered to be detrimental. To understand the better his idea, we give it in his own words:

"I think the candid reader will agree with me that standards of discipline and prescribed methods and modes of culture are but a negative advantage, and probably do more to elevate the mediocre talent of the land into quasi dignity and supposititious influence than the lack of them tends to degrade the talent and defeat the success of the true genius. It is not, therefore, an unmitigated evil that we are considering, nor one that calls for a struggle such as would be demanded were we confronting an evil that threatened with destruction our professional principles and promises of legitimate prosperity."

"Now, the special evil that we have under contemplation, due to imperfect appreciation of the necessity of such action as will promptly elevate the standard of medical education, is one that we may find to be far less intolerable than has popularly been supposed. If any one suspects that I presume to be an apologist for evil, let it be ever so trifling in amount and mild in character, a grave mistake has been made. His judgment or my statement of views is at fault. I trust it will be seen that I recognize differences in the grades and pernicious qualities of the evils that afflict mankind, and also that I perceive the force of some reasons why the present system of obtaining medical education and of allowing the standard of acquirements to remain dwarfed has fewer disadvantages to the public and the profession than many good people imagine. An evil of weight and importance it is, and an evil of its present magnitude it will remain until the spirit of truth and honor arouses the head and heart of the profession to do that which will quench the bad and develop the good. It is, however, an evil that, for some reasons which I will endeavor to point out, is working powerfully in a direction parallel to that which craving reformers dream about and hope some time to realize in fact."

Whatever interpretation may be made of his views, we have no doubt that he means what he says, and if the subject is not made clear, it is evidently not on account of any lack of pains on his part to make it so.

Pursuing the subject still further, we are impressed with the idea that our writer is quite satisfied with the present facilities of acquiring medical education; that, in fact, our present system is a blessing in disguise. The prevailing system appears also to help the public in discriminating between the ordinary physician and the genius, and therefore is to be commended. Although this ability on the part of the public to separate the sheep from the goats may be questioned, we allow it for the sake of the argument and quote what appears to be one of the conclusions:

"If the world were still plunged in mediæval mental darkness, there would be no justice in any assumption of a superficial medical curriculum being a tolerable evil, for at best it would be a cruel imposition upon the people, and at the worst a remorseless scourge of the class who sicken."

Therefore, there seems to be no need of trying to improve our methods of teaching, of aiming at any higher standards, of taking any advantage of past experiences in medical education, as we can safely rest the matter with the public and the student. If the latter is unable to overcome the small obstacles which beset his path, he has no business to be a physician, and the discriminating public will soon find him out. Thus the evils of imperfect medical education correct themselves, and give us "plenty of room up aloft." As an incentive to look in that direction for success, we are informed that "he who seeks the professional aid of the loftiest is pretty sure to seek that which is efficient, and which will not be withheld from him;" and then, after a concluding sentence, follow the name and office address of the writer.

#### HOMEOPATHIC DOINGS.

THE thirteenth annual session of the Homeopathic Medical Society of Pennsylvania has lately been holding its sessions in Philadelphia. I. C. Burgher, M.D., of Pittsburg, President of the Society, delivered the opening address upon the progress of the homœopathic profession. Some of his statements are a source of great amusement to us. It was worthy of note, he thought, that the literature of the old school was gradually becoming seasoned with the therapeutic principles of the new method. Its practice was improved by the substitution of small doses in place of large ones. As an example of the growing use of uncombined remedies, he instanced *the gelatine-coated pills*, extensively advertised in old school medical journals, *each one containing but a single drug, also the wafers containing remedies uncombined.* (The italics are our own.) Plans of treatment that had been taught for ages had been almost set aside. Three hundred regular graduates had swelled the ranks of the profession, besides *an indefinite number of recruits from the old school.*

The harmony of the proceedings was somewhat marred at one part of the session. A paper was read on "Skin Diseases and their Treatment." One physician objected strongly to the use of a certain remedy, which he declared to be allopathic in character. "I have no objection to this gentleman's criticism upon my paper," said the author, "but he also uses 'combined remedies.'" The physician angrily denied the assertion in language more forcible than decent, and for a time there was considerable unpleasantness, but it was subsequently patched up by the offering of an apology and its acceptance.

Another point worthy of reference in connection

with the meeting in question, is the enactment of the following rules for persons applying for admission as medical students:

*First.* The candidate shall be of good moral character and unquestionable sobriety, and shall give satisfactory evidence of studious habits. *Second.* That he shall possess, or previous to commencing the actual study of medicine shall acquire, a good English education, together with a fair knowledge of mathematics, natural philosophy, and the rudiments of the Latin language. *Third.* That he shall enter into an agreement with his preceptor to attend not less than three terms of college and hospital lectures, and to devote the intervals to regular and systematic study. *Fourth.* That all our colleges should fix the requirements for graduation at such a standard as an ordinary student ought to be expected to attain by a three-term course of study, and that the final examination should extend to the practical skill of the student in all the departments where such an examination is practicable and such skill valuable to the practitioner.

We wonder whether the disciples of Hahnemann would claim that this system had been borrowed from them by our friends in Philadelphia.

#### ALBANY ETHICS.

THE faculty of the Albany Medical College appear to be carrying on a very brisk business in advertising its members in the different local papers. There is a deliberation about the matter which must cause the luckless practitioners outside of the College Ring to cry for mercy. In nearly every one of the Albany daily papers there are accounts of so-called wonderful operations performed by some one of the college professors at the St. Peter's Hospital. We are quite willing to believe that the college has a good faculty, that the majority of its members are men of more than ordinary ability, but we know that they do not comprise all the talent of the place. Hence, we think that the advertising dodge should not be a monopoly. Of course we cannot imagine that any of the operators are guilty of describing their own operations, for this is known to be unprofessional, yet we are at a loss to explain the curious coincidence of accounts of such operations appearing verbatim in all the papers at once. An occasional squib concerning a notable case might be excused as accidental and due to some enthusiastic admirer of the operator, but the way this thing is done in Albany burlesques the very idea of apology or excuse. Not only are cases operated upon regularly reported, but they are announced beforehand, with the name of the operator, and in some cases his method of procedure. The members of the faculty need not be told that this is a gross violation of their privileges, and an outrage upon their brethren outside the college, not only in their city, but throughout the country. The Code, which we believe is as binding upon this faculty, as upon the profession outside, is quite explicit

on this point, and we take the opportunity to quote and to apply it:

"It is derogatory to the dignity of the profession to resort to public advertisements, or private cards, or handbills inviting the attention of individuals affected with particular diseases, publicly offering advice and medicine to the poor gratis, or promising radical cures; or to publish cases and operations in the daily prints, or suffer such publications to be made; to invite laymen to be present at operations, to boast of cures and remedies, to adduce certificates of skill and success, or to perform any similar acts. These are the ordinary practices of empirics, and are highly reprehensible in a regular physician."

## Reviews and Notices of Books.

CYCLOPEDIA OF THE PRACTICE OF MEDICINE, VOL. XII. Diseases of the Brain and its Membranes. By Prof. H. NOTHMAGEL, of Jena; Prof. E. HITZIG, of Zurich; Prof. F. OBERNIER, of Bonn; Prof. O. HEUBNER, of Leipsic; and Prof. G. HUGUENIN, of Zurich. Translated by HENRY R. SWANZY, M.D., of Dublin; CHARLES EMERSON, of Concord; EDWARD H. BRADFORD, M.D.; ELBRIDGE G. CUTLER, M.D.; ROBERT T. EDGS, M.D.; JAMES J. PUTNAM, M.D.; FREDERICK C. SHATTUCK, M.D. and S. G. WEBBER, M.D., of Boston; and LOUIS VELDER, M.D., of Elmira. ALBERT H. BUCK, M.D., New York, Editor of American Edition. New York: William Wood & Co., 27 Great Jones Street, 1877.

As we see by the title-page, the German editor has been fortunate in securing for this volume writers whose reputations have already been made by their literary productions in the field of neurology: Notnagel, by his investigations on vaso motor nerves; Heubner, by his "Syphilitic Diseases of Cerebral Vessels;" Huguenin, by his "General Pathology of the Nervous System," of which the first volume has appeared; Hitzig, by his "Researches on the Brain;" and finally, Obernier, by his "Experimental Researches on the Nerves of the Uterus," and other allied studies.

The first 228 pages are taken by Notnagel, who treats of anæmia and hyperæmia of the brain, general intracranial hemorrhage and occlusion of the arteries, veins, and capillaries. Cerebral anæmia appears to have been little understood in the past century, when excellent pathologists held the views of Kellie and Monroe, that as long as the skull remains intact, the quantity of blood is always the same. The erroneousness of such a doctrine has been shown by Donders, Robin, and others, who have found that the amount of blood is regulated by the cerebro-spinal fluid, the contents of the perivascular spaces, the thyroid gland, etc. The author shows his usual caution in stating that the positive experiments of Schiff and Goltz, pointing to the existence of nerves directly dilating the blood-vessels, do not altogether rest upon an established foundation, nor do the negative experiments of Jolly have much weight. He holds it probable, however, that such nerves do exist. It is noticeable that he agrees with Obernier in stating that sun- or heat-stroke is certainly not due to the direct influence of the sun, but to an abnormal increase in the temperature of the body—an opinion which is somewhat at variance with those that are usually held.

Cerebral hemorrhage is the name he has substituted for apoplexy, a change we should now be prepared to accept; for, in fact, apoplexy denotes merely a clinical symptom. The causes of the affection are well summed up, and the two main predisposing conditions are stated to be increase of blood-tension and disease of the walls of the vessels, especially of the arteries, and chiefly in consequence of the rupture of the minute aneurisms that Charcot and Bouehard have called *miliary*. The morbid process consists in a chronic periarteritis. As for the matter of atheromatous degeneration, which has held such an important place as a cause of cerebral hemorrhage, it is thought to rarely have such a relation, and only in the arteries at the base of the brain and their branches. Atheromatous degeneration does not in itself lead to rupture, and in this connection an important point is brought into notice, viz., that rigidity of the peripheral arteries is not of importance in the diagnosis of cerebral hemorrhage. Another interesting point, borne out by the statistics of Ferriels and Dickinson, is, that the causal relation between contracted kidney and cerebral hemorrhage is not shown. He agrees with Eulenburg further, that certain forms of hypertrophy of the left ventricle may cause hemorrhage when they are associated with increase in arterial pressure. A certain class of diseases of the blood, as pernicious anæmia, may be a cause. Whether the apoplectic or plethoric habit, characterized by broad chest and shoulders, short neck, large abdomen, and rubeund complexion, is a fact of much note, he is inclined to doubt. Practically, poorly nourished and thin persons are just as apt to be attacked—and indeed, the real cause is entirely independent of such habit, being essentially a disease of the arteries. Cerebral hyperæmia is favored by the habit in question, and it is doubtless this condition which occasionally leads to hemorrhage that has been confounded with the latter. The lesion is usually in the corpus striatum, and the paralysis on the side opposite the lesion, and though cases occur, as those of Brown-Séguard and others, where the paralysis or paresis has been on the same side, they are infinitely rare. The cause of this remarkable fact in such exceptional cases is still a mystery. As for the question of the localization of hemorrhagic lesions, certain groups of symptoms point with approximate certainty to the pons, the pedunculus, the nucleus lenticularis, and the crura cerebri. In the other regions of the brain the most careful consideration will only establish a presumptive diagnosis, and sometimes not even this. The subject of the occlusion of vessels and softening, a matter that owes so much to Virchow, has been well worked up, and Notnagel has shown a talent, which is certainly not German, for summarizing in a clear way the most important facts about these obscure matters. A short sketch is given of marantic thrombosis, which does not originate in a condition of phlebitis, but where the action of the heart is feeble, as in children under one year, in the collapse of sudden diarrhœa, and in the exhausting diseases of adults. It occurs chiefly in the longitudinal or transverse sinuses. Other thrombosis of cerebral sinuses are due to phlebitis, and the existence of a primary or idiopathic thrombosis may be a matter of grave doubt. Notnagel certainly deserves the reputation of having handled his portion of the volume in a masterly style, and made it both palatable and digestible. Tumors of the brain, by Professor Obernier, are treated upon the anatomical basis proposed by Virchow, which, after all, seems destined to serve us for a long time to come. As a point in diagnosis, he emphasizes the fact that there is always

aphasia when the tumor is situated on the left side, in the region of the island of Reil. The diagnosis of intracranial tumors may be impossible; for the symptoms to which they give rise are for the most part those produced by other diseases of the central nerve-system. The author evidently is strongly impressed, however, with the idea that in the early stages the condition of the optic papilla, retina, and field of vision, are safe guides in making a diagnosis. According to Heubner, syphilitic growths in the nervous system do not usually occur until several years have elapsed from the time of infection, though this rule has its exceptions. Parts of the body that are preternaturally weak, or have been injured, are most liable to attack. Syphilitic diseases of the cord may be grouped under neoplasms, callus (or connective tissue formations), and softening, though the latter subdivision is questionable. Four hundred and seventy-five pages are devoted by Huguenin to inflammation of the brain and its membranes. He employs the term *lepto-meningitis* to avoid some of the misapprehensions which gather about acute hydrocephalus (without tuberculosis). The conditions which produce it are varied, and are: fluxions of the brain and pia, general dropsy, effusions in marasmus, special affections of the brain, venous stasis from various causes, and local obstruction to the escape of blood from the cranium. Under the heading of *meningitis tuberculosa* or *basal meningitis* or *acute hydrocephalus (tuberculous)*, the author gives a succinct summary of the views held at present about tubercle. The rich experience of the author has enabled him to form some original views about *pachymeningitis interna*, in which he differs somewhat from Virchow and modern pathologists as to the way in which the membrane forms. Hitzig takes the last sixty pages of the book. His articles on *Hypertrophy and Heterotopia of the Brain* are chiefly interesting in a pathological point of view, as the conditions are only recognized with certainty at the autopsy; lastly, *Dementia Paralytica*, the final article, is pleasantly written, and gives a clear and simple description of the disease in all its phases.

In closing the volume the reader will realize that he has been presented with a very large number of new facts and original reflections served up with much careful and precise reasoning, and that an obtuse subject has been skilfully handled, and at the same time been made attractive and practical.

## Reports of Societies.

### MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Sept. 24, 1877.*

DR. JOHN C. PETERS, *President, in the Chair.*

#### ANALYSIS OF THE EXAMINATION OF SEVENTY-SEVEN PREGNANT WOMEN, WITH A SYNOPSIS OF THEIR LABORS.

DR. P. BRYNBERG PORTER read the analysis, which, in addition to the many points noted in the examinations, contained remarks relating thereto. A few items were abstracted as follows:

##### MENSES.

In two instances menstruation occurred once after gestation had commenced.

In one case the menses appeared three times after conception had occurred.

The earliest age at which menstruation had commenced in any of the cases was eleven years. In one case menstruation returned about six weeks after confinement, and continued regularly throughout lactation.

##### QUICKENING.

This occurred in all except one.

##### MORNING SICKNESS.

It was present in 46 cases, but in none produced sufficiently urgent symptoms to call for the induction of premature labor.

##### AREOLA.

It was frequently noticed not to be symmetrical in the same patient.

The secondary areola was not well developed in the blonde. Areola well marked in 68 women.

##### FETAL HEART.

The fetal heart was heard distinctly in 72 cases; in one case no examination was made with reference to this point.

##### CERVIX UTERI.

The cervix was apparently long in 40 cases; 21 multiparæ and 19 primiparæ. One-half an inch in length was regarded as long. The cervix was soft in 37 cases. In 41 cases the external os was found patulous; in 15 to such an extent as to admit the finger.

##### URINE.

The urine was examined in 60 cases, and in only one was albumen found. In that case there was no œdema whatever, yet convulsions set in at the commencement of labor.

In another case, the patient suffered severely from dyspeptic symptoms and had marked œdema, yet not a trace of albumen could be found in the urine. After labor had commenced, the urine was found to contain a large quantity of albumen. A short time after labor her general condition seemed to be good, but it was not long before unfavorable symptoms were developed and the woman died. The kidneys were found in the advanced stage of nephritis.

##### KYESTEINE.

This was noticed in almost every case.

##### PREVENTION OF POST-PARTUM HEMORRHAGE.

This was incidentally referred to in connection with the note that such hemorrhage occurred in seven cases not under the doctor's care. There were three factors in Dr. Porter's method of prevention:

1. The exhibition of ergot just before the birth of the child, and immediately after the delivery of the placenta.

2. Introduction of the fingers into the uterus, perhaps entire hand, to remove all clots and stimulate the organ to contract.

No ill results had been seen to follow such practice.

3. External manipulation over uterine tumor until the binder is applied.

The paper being before the Society for discussion, DR. ISAAC E. TAYLOR remarked, with reference to the occurrence of pigmentation in various parts of the body of the pregnant woman, that it was once looked upon as being a very important sign of pregnancy; so much so that Dr. Wm. Hunter felt willing to decide whether a woman was pregnant or not from this symptom alone. That, however, was an error. For,

many cases of pregnancy occurred in which there was no discoloration of the areola of the nipple, and pigmentation was not seen elsewhere upon the body. What was the cause of the pigmentation when present?

Dr. Taylor was of the opinion that it depended upon some disturbance of the supra-renal capsule incident to pregnancy.

Regarding the changes which occur in the cervix uteri during gestation, Dr. Taylor's remarks can be found on page 644.

A MEMBER remarked that he had made observations with reference to the number of fetal heart-beats to the minute, and the sex of the child, in 60 cases. In almost every case he had been able to predict correctly concerning the sex of the child by regarding it as a male if the heart-beats numbered less than 130, and a female if they numbered more than 130 to the minute.

DR. WEBER related the history of an interesting case of labor, after which the Society proceeded to the nomination of officers.

## New Instruments.

### A NEW TENACULUM-NEEDLE, NEW WIRETWISTER, AND A NEW MATERIAL FOR SUTURES.

By C. J. CLEBORNE, M.D.,

Surgeon U. S. Navy.

THE instrument figured in the accompanying wood-cut was suggested by the difficulty sometimes experienced in manipulating the ordinary surgeon's needle, especially when insecurely held, and imperfectly directed by the *porte-aiguille*. The canula needles of Eve of Nashville, Simpson of Edinburgh, Statin and others, as well as the modified instruments of Tiemann and Bryant, are all more or less objectionable. Tiemann's arrangement is very ingenious, but the wire is apt to kink, the needle to bend, and the whole apparatus is too bulky and inconvenient for general use. The same faults are found in all other needles formed of *tubing* simply soldered on a shoulder—weak points—unless made of heavy material. It occurred to me to utilize the tenaculum of the pocket-case, by hollowing its *solid* shaft to form a *finer* needle, and thus combine two instruments in one. The advantages of this plan are obvious, as the most delicate tubular needle can now be made of sufficient strength, and patients may be saved the painful and tedious process of dragging wire, silk, or thread through the tissues. It can be made of any size, curve and calibre to suit horse-hair, cat-gut, double wire or silk, and will be found useful in operations upon hemorrhoids, vesico-vaginal fistula, the mouth and perineum. The difficulty in passing silk or thread through canula-needles may readily be obviated by partially untwisting the end of the suture, dipping it into *collodium*, and then rapidly re-twisting it taut between the fore-finger and thumb. This does not occupy more than a few seconds, and when dry, the end is sufficiently stiff to pass through the needle-tube. A still better plan is to harden the end by sulphuric acid and ammonia, and ligatures thus prepared may be obtained from Tiemann.

I have used with great satisfaction sutures made

of the finely finished three-ply thread known as "Hard-ash." It is very strong, creates less irritation than silk, does not need waxing, and is particularly well fitted for tubular needles. Like other vegetable fibre, it may be *cellulosed* by dipping for a few seconds into a mixture of sulphuric acid and water (two volumes of the former to four of the latter), then washing and neutralizing the acid with dilute ammonia. The texture is at once changed into an unalterable material analogous to animal membrane, which increases in toughness and flexibility by moisture, and is superior to catgut or other animal ligature.

The wire-twisters of Dawson and of Coghill cause some delay in rapid operations. I have therefore devised a more simple form.

The wood-cut represents an instrument which combines: a tenaculum A, a curved needle (for wire or silk) B, (which may also be used as a staphylo-rhaphy needle and sutured hook), a straight needle for wire or silk D (suitable also for exploring), and a small figure-of-eight-wire-twister C, which can be quickly and easily applied. Silver or other suture-wire, if run through the tenaculum needle, will be evenly and neatly coiled.

The combined instrument (which fits the ordinary pocket-case) is made by Messrs. George Tiemann & Co., of New York, to whom I am indebted for the compact and handsome style in which it is manufactured.

### A NEW DEVICE FOR SPREADING PLASTER-OF-PARIS AND OTHER SUBSTANCES UPON BANDAGES.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: In the preparation of permanent casings, by what we will call the old method (by hand), the time required, as well as the dirt and inconvenience arising therefrom, has, no doubt, to a great extent precluded their use.

Dr. Frank H. Hamilton remarked to a delegate at the Chicago Convention (Dr. Wm. A. Bird), "that one of the greatest drawbacks to the use of the *plaster-of-paris bandage* in the treatment of fractures, was the length of time occupied in preparing them." This is indeed true of plasters and all other substances used for the purpose. Say, for instance, we have a fractured femur, nine six-yard plaster bandages are required to form a complete and firm casing. The most expert manipulator of this substance finds it impossible to prepare a single six-yard bandage in less time than fifteen or twenty minutes, and after it is prepared the plaster is unevenly applied; besides, requiring an expert to spread the material thus imperfectly.

The failures recorded, of the plaster not hardening properly, may be traced, I venture to assert, to imperfect preparation (by hand), the water of crystallization being unequally distributed, in consequence of irregularities in the layer of plaster.

Besides the great length of time required to simply apply the plaster to the cloth, the dirt is a matter of

some importance. The plaster, being highly calcined, lies over everything if only slightly agitated—an objection as formidable as the time occupied in preparation.

About six months ago I conceived the idea of overcoming—if possible—this obstacle to the great modern acquisition to surgery, and to that end I set about constructing an apparatus, which has since been received with marked favor by several eminent surgeons north and south. I feel confident that the objections to plaster-of-paris, as well as to other substances as applied simply to the preparation of the

bandages, are entirely removed by this device, and that permanent castings, by its introduction, are likely to gain a still greater degree of popularity.

The apparatus is constructed to simply roll bandages, or, if desired, to apply silicate of soda,

dextrine, or plaster, simultaneously with the winding process. The accompanying cut shows the apparatus in position—ready for use, and will convey a much better idea than can possibly be done by an attempt at description.

It is inclosed in a very neat polished black-walnut box, with brass fittings, confines the material to the box, therefore creating no dirt. Eight minutes is all that is required to prepare nine six-yard bandages of ordinary width; formerly, by hand, two and a half hours were occupied in accomplishing the same object. The only knowledge necessary, in order to work it successfully, is to know how to turn a crank, which the office boy can do as well as the surgeon. As the cost of instruments is a matter to be taken into account—especially these hard times—as a matter of information to my fellow-practitioners, I will state that the entire cost of the device will not exceed \$5.00, which places it within the reach of all practitioners and hospitals. Without intending to overrate one's own invention, I must quote the words of my distinguished contemporary, Dr. J. L. Little, of New York, "that it ought to and will come into general use."

Respectfully yours,

FRANK GREENE, M.D.

COLUMBIA, S. C.

DR. W. R. WHITEHEAD, formerly of this city, and lately of Denver, Col., has removed to Paris, France, to practise in that city. Dr. W. is a graduate of the University of Paris.

**OFFICE THEIVING AND PROFESSIONAL FRAUDS.**—The following letter is sent to us by a physician of this city:

"Should you have space to spare in your columns, I would like to take advantage of it to warn physicians of New York and elsewhere against a peripatetic fraud, who endeavors, under the name of Dr. T. W. Flanner, to obtain money upon the pretext that while travelling through the city he has been the victim of pickpockets. He merely wants a few dollars to reach friends in Baltimore or Washington, on his way to his home in Springfield, Mo. Perhaps he varies the name and the story as he enters upon new fields of operation. It may be wholly superfluous and unnecessary for me to remind you that Dr. T. W. Flanner, of Springfield, Mo., is a gentleman of good standing in business, professional, and private life, and this unwarranted assumption of his name and title is as annoying to him as it is beyond his control. The unfortunate "victim of pickpockets"—himself one of their guild—is of fine appearance, gentlemanly manners, apparently about fifty years of age, and uses the Quaker's "thee" and "thou." With the cruel hope that this may be sufficient to ruin his business, I remain,

"MULCTED."

**THE THIRD ANNUAL MEETING** of the Indiana, Illinois and Kentucky Tri-State Medical Society, will be held in the city of Evansville, Ind., Oct. 16, 17, and 18, 1877.

W. H. BYFORD, A.M., M.D., *President.*

G. W. BURTON, M.D., *Rec. Sec.*

DR. FRANK H. HAMILTON will hold his surgical clinics at Bellevue Hospital every Wednesday during months of November and December, at two and a half (2½) P.M.

PROF. F. N. OTIS gave a reception at his residence, to Prof. Pease, of Syracuse, on the evening of September 26th.

**PORTABLE FOOD FOR HORSES.**—The *Journal de St. Petersbourg* furnishes the following details regarding the preserved food for horses, prepared in the event of scarcity of oats, or in case the transport of the food as used at present should prove too difficult. This food is composed of pounded oats and gray-pea flour, mixed with hemp-seed oil and salt. The paste obtained by this mixture is then cut up into thick cakes of about four inches in diameter, pierced with small holes to assist the soaking in water. On being taken from the oven these cakes are strung upon wires, so that each wire holds the daily ration for a horse. Each ration, of the weight of four pounds, is equal in nutriment to ten pounds of oats. It is stated that the horses are extremely fond of these cakes, whether soaked in water or quite dry; and although, when fed exclusively on these cakes, they become thinner in appearance, they do not lose any of their strength, though hard-worked.

**YELLOW FEVER AT FERNANDINA, FLA.**—Fernandina has for some time past been in a very filthy condition. Eleven hundred cases have been under treatment, with fifty deaths. The ravages of the plague are now rapidly taking in the colored people, who of late years seem to have lost their immunity from this disease.

**A CENTENARIAN.**—The oldest inhabitant of Cairo, Egypt, died last July. She was a negress and was 106 years of age. She was in full possession of her faculties up to the very last, and was particularly noticeable for a remarkable memory.

## Original Lectures.

### LACERATION OF THE CERVIX UTERI, AND ITS TREATMENT.

BEING A CLINICAL LECTURE

By WM. GOODELL, M.D.

CLINICAL PROFESSOR OF GYNECOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

(Reported by S. M. Miller, M.D.)

THE cervix uteri, as you all know, has to expand enormously in the process of labor. Either by the impatience of the attending physician to get away, or of the woman in labor to hasten the birth of the child, or from other natural causes, it often happens that the membranes are ruptured prematurely, and the head of the child forced through the undilated os, thus giving rise to a laceration which is often difficult to diagnose, and so may pass for a long while unnoticed. If the laceration takes place on the anterior or the posterior part of the cervix, it generally heals naturally; for the movement of the cervix is, for the most part, forward and backward. If, however, the laceration be lateral, or bilateral, it is not by any means so likely to heal of its own accord. The mucous membrane of the cervical canal is studded with glands and follicles, and covered with pavement epithelium. The backward and forward movement of the torn lips of the cervix, by attrition on the vagina, then produces an erosion of the surface of this epithelium, which is now exposed to injury. When, therefore, a woman comes to a physician, complaining of leucorrhœa, of pelvic weight and pains, and of other uterine symptoms produced by this injury, a superficial examination reveals merely the denuded cervical canal, and he is but too likely to overlook entirely the graver injury, and treat simply the apparent erosion. He applies nitrate of silver, or touches the raw surface with nitric acid, or makes use of astringent suppositories, and very possibly the leucorrhœa disappears, the other symptoms improve, and the patient gives up treatment, thinking herself entirely cured, only to return soon again with an exact repetition of the symptoms. Ninety-nine out of a hundred doctors will mistake laceration for erosion, and will treat it accordingly—that is, mistreat it. I have myself made just the same blunder. The proper way in which to diagnosticate laceration of the cervix is, apart from a careful digital examination, to draw the anterior and posterior lips of the womb together by means of tenacula; and if, in so doing, you are able to reduce the size of the cervix, and cause the supposed erosion to disappear, you may be tolerably sure of the existence of a laceration. Of course this state of affairs calls for a very careful examination with the speculum. In recent cases of this accident—that is, during the lying-in state—there is usually more or less cellulitis, and the pulse is high and feverish. There will be pain in the iliac fossa, the temperature will remain high, and the woman's convalescence will be slow and imperfect.

I bring before you to-day a woman suffering from the effects of a laceration. She was delivered, last December, after a somewhat difficult and tedious labor, of her first child, and ever since then she has been complaining of bearing-down and pelvic pains, and of frequent leucorrhœal discharges. These symptoms come from a subinvolution of the uterus, and she will never get well until this lacerated cervix is cured. I have placed the patient on her left side, with her hips

well to the edge of the table. She has, as some of you can see when I expose the womb, a laceration on each side of the cervix. Now, this is a very unsatisfactory operation to perform before a class, and particularly as the light to-day is very poor. You can see very little of what I am about to do, and must rely entirely upon my fragmentary explanations as I go along. I say that when you have discovered this state of things you must proceed at once to an operation. Some women in this condition may get through a great many years without any suffering to speak of; but if there be any complication—like subinvolution of the womb, for example, which is usually present—there can be no such thing as recovery without an operation. Sims's speculum is the best instrument for this, as well as for other vaginal and uterine examinations and operations. Having inserted this speculum and dragged the womb down by a double tenaculum, I shall at once proceed to denude the torn surfaces (which have long ago healed in ragged edges), and bring them into accurate apposition before I introduce my stitches.

Now, this is very easy to state in words, but not so easy to execute, for the vagina is a narrow place to operate in, and the flow of blood will greatly obscure the parts. I see that the woman is now entirely under the influence of the ether, and so I begin by taking hold of the two split lips with tenacula, and by bringing them together so as to map out my field for denuding the surfaces. The womb is a highly vascular organ, and I may have some very troublesome bleeding. I ought to have brought a small wire *crêpeur* with me as a tourniquet for the cervix; but I forgot it in my hurry, and so have improvised this wire loop at the end of a wire-twister, which I think will answer very well in its stead. I begin denuding on the anterior lip, which, from the position of the woman, is the lower one; for, if I began above, the flow of blood might seriously interfere with my work below. I am trying to pare off both surfaces of one side in one single piece, so as not to leave any portion undenuded. This cannot always be done; but, whatever plan you adopt, be sure not to leave any little islets of undenuded surface. They will inevitably prevent union. It is no easy matter to work here in the angles; the circular artery of the cervix runs very near this lower angle, so I must be doubly watchful here, and merely skim off the surface. For this operation we are indebted to Dr. Emmet, of New York, who first devised it some ten years ago. Quite recently I performed this same operation upon a lady, in whom, at the first examination, made some years ago, I failed to rightly diagnosticate the trouble. She had a retroflexion of the womb, caused by the laceration. The cervix is one of the props of the womb, and, of course, when it is lacerated, one of the main supports of the uterus is removed, and it wobbles about in all directions. I treated this lady for her retroflexion with pessaries, but without the expected prompt relief. She was barren, and her mind was so affected that she was really afraid to go out into the street by herself. I lately had the opportunity of making another examination, and found out my blunder. When a woman wishes to have children, what she will go through with to have them is only equalled by what she will undergo so as not to have them when she does not wish them; so she cheerfully submitted to the operation. The cervix united at every stitch, and when I last heard from her she was wholly well, both mentally and physically. I expect soon to receive a letter from her announcing her pregnancy. Now, just here, in passing, let me call attention to the wonderful in-

fluence which a disordered womb has upon its possessor's brain. This poor lady was made utterly wretched by this laceration: nervous, easily frightened, unable to sleep at night—in fact, almost insane. And notice how completely her health of body and of mind was restored by the operation. While talking to you my hands have been busy denuding these surfaces, and, as it is hard to be doing two things at the same time, you must excuse me if I speak somewhat incoherently. Thus far there has been but little bleeding, so I have been working rapidly. You must be careful in this operation not to denude the whole surface of each lip, but to leave a portion in the middle of each one untouched, else the cervical canal would be wholly closed. Let me give you a bit of advice as I am working. I said that lacerations of the cervix were often produced by premature rupture of the membranes. When the woman in labor is a multipara, you may generally rupture the membranes with impunity after a fair dilatation of the os. But in the case of a primipara you must not rupture them until full dilatation has taken place. There are, of course, some exceptions to this rule, but it is a good general one. See now how small the cervix becomes when I bring these raw surfaces together with my tenacula! I think that I may now begin to put in my stitches. What has been the preparatory treatment in this case? I have had tincture of iodine applied over the surface of the cervix, so as to reduce the engorgement. Hot-water injections have also aided in making the parts more healthy. The woman's bowels have been thoroughly opened. And now, before beginning to pass my stitches through, let me show you how to avoid the trouble of continually threading your needle for each stitch. I have passed a piece of fine silk thread through the eye of one needle, and tied a half-knot in it. In making my stitches I pass the end of the wire through the loop of the thread, and simply bend it over. The wire then follows the loop. I use a round and not a surgeon's needle for this purpose, because it cuts less and causes less hemorrhage. As my needle is, of necessity, blunted slightly each time it comes in contact with the speculum, as it occasionally will, I blunt but one needle, and do not injure three or four, as I have often done in the course of a single operation of this kind.

The needle must have a very short cutting edge. I shall make about three stitches on each side, putting the needle in well back from the edge, so that the stitches will not tear out. A needle-holder is indispensable here. I have put four stitches on one side, and three on the other; I think that is enough. In fastening the stitches I use perforated shot. Some excellent surgeons object to this mode of securing the wires, but, perhaps from habit, I prefer it; at any rate, I have never found any harm coming from it. What force should be employed in pushing the shot home on the wire? I make use of considerable tension—enough to bring the raw surfaces into accurate apposition. In cutting off the ends of each wire after clamping the shot, I sever them close enough to the shot to shave off a thin film of the lead with the scissors. This prevents points occurring which might wound the vagina. With regard to the after-treatment of this woman, I shall give instructions that enough of opium be given to lull any pain she may have, and, more important still, to prevent any movement of the bowels for at least a week's time. Any movement on the part of the bowels might seriously interfere with the due process of healing by first intention. She must be kept in bed for two weeks. Eight days from now I shall remove the stitches. Her water, too, must be carefully drawn during this period. Some

women can't pass their water when lying on the back, and even if they could, it would not be advisable to thus allow the possibility of a small portion of the urine finding its way into the vagina and setting up an irritation on the raw surfaces of the wound. If any offensive discharge shows itself, I shall have the vagina carefully cleansed with solutions of the permanganate of potash or of carbolic acid. Cases of this kind, if not promptly attended to and cured, may result in some of those dislocations of the uterus, in which that organ hangs wholly outside of the body. I forgot to warn you at the proper time to be careful to get all clotted blood out of the wound before running the shot down upon the sutures. If at any time during the operation the hemorrhage be alarming (this has been a comparatively bloodless one) the wire-loop tourniquet placed around the cervix will temporarily arrest it. The final adjustment of the stitches will usually permanently stay it.

But suppose that a secondary hemorrhage takes place, as it occasionally will, what is now to be done? You must insert a speculum, and plug up the vagina in the manner that I am about to illustrate, with my thumb for the cervix and my assistant's hand closed around it to represent the vagina. With wet and flat pieces of cotton, not larger than a silver dollar, you will firmly pack the upper portion of the vagina all around the cervix, until the layers of cotton reach the os. Then fill up the rest of the vagina so as to keep this important upper packing from becoming displaced. In this way you not only effectually tampon the vagina, but you bring the stitched surfaces in closer relation to one another, and, consequently, in the best possible condition for uniting.

From want of room and from the inaccessibility of the parts, all plastic operations about the womb and the vagina are very tedious ones. I have been, more than once, over two hours in closing a vesico-vaginal fistula. The temptation of an operator before a large class of students is to hurry through with his work, yet you see that it has taken me my whole lecture hour to perform this operation.

### THE NATURE AND TREATMENT OF NEURASTHENIA (NERVOUS EXHAUSTION), HYSTERIA, SPINAL IRRITATION AND ALLIED NEUROSES.

By GEORGE M. BEARD, M.D.

PART II.

(Continued from page 585.)

I HAVE lately had my attention directed to two other cases of hay fever, where the attacks were brought on through sexual irritation: in one, excess in intercourse; in the other, a seminal emission would create the paroxysms on the following day.

The vicariousness, interchangeability, and correlation of these neuroses, is one of the most significant and suggestive facts in medicine. Thus, when hay fever appears, sick headache disappears, and again recurs when the hay fever has completed its course. Nervous dyspepsia likewise takes the place of sick headache, and is replaced by it. Several cases have been reported to me where a severe attack of nervous dyspepsia followed recovery from an attack of hay fever, and in a large number of instances hay fever has disap-

peared almost instantly on the appearance of diarrhoea or dysentery. Dr. Lente tells me that he saw this summer, at Saratoga, a lady in an attack of cholera morbus, which for the time caused her hay fever to vanish utterly. I have known pain in the back of the neck to change suddenly into pain in the epigastrium. Inebriates and opium-takers seem to suffer less from other maladies than if they were not slaves to their habits.\* It is possible, indeed, for one to suffer from nearly all of these neuroses at once, the symptoms skipping about from one part of the organism to the other, under the influences of changes in habits or environment, or through mental influence. The symptom of spinal irritation especially comes and goes like the wind; this evanescence and changeability of the symptoms is one of the leading signs in the differential diagnosis of these neuroses. In the majority of organic or structural diseases of the brain, spinal cord, or peripheral nerves, there is a fixity and permanence to the symptoms as regards locality, though they do not endure all the time. An illustration that I have sometimes used to make clear the distinction between functional and structural diseases is the well known double tree that was formerly pointed out to travellers on the stage route between Ticonderoga and Lake George. Two trunks grow up side by side, so close together and so similar as to appear but one tree, but at some distance from the ground they gradually separate, and each branches out by itself, one into an oak, and the other, I believe, into an elm. So, functional and organic diseases in many of their early symptoms are so nearly alike as to seem practically identical; but in their middle and later stages they diverge widely, so as to have little but pain in common. One of the earliest signs of their divergence is the fluctuating character of functional symptoms as compared with the stable character of organic symptoms. This point is practically of the highest moment, since the evanescent, fleeting and metastatic symptoms of these neuroses are very often mistaken by the profession and the people for symptoms of organic disease, and thus needless fear is felt. A physician of large experience and unusual accomplishments once consulted me in deep depression and alarm on account of certain symptoms—as twitchings of the muscles, spinal irritation, and neuralgia—which he feared indicated structural disease of the cord. I told him that he could not get up an organic disease of the cord if he tried; that while there might be hysterical and other functional symptoms in organic disease, yet, as a rule, those who have one kind of malady do not have the other; and that functionally diseased subjects are far less likely to have organic disease than those who are not so diseased. These disorders frequently act as safety-valves to the system, and thus become disguised blessings. Notably, sick headache appears, in some cases, to be a kind of waste-pipe through which nerve-perturbations escape. Hay fever acts in a similar way in some cases, although in others it produces exhausting effects. Many who suffer from it are comparatively well during the portion of the year when the attack is not upon them, and also get rid of many nervous symptoms that annoyed them before they became victims of hay fever.

\* In this series of papers I have assumed that hay fever and inebriety are neuroses, although I am not unaware that all have not yet sufficiently studied this subject to understand the arguments by which these claims are demonstrated. Those who wish to look further into the subject are referred to my paper on "New Facts and Suggestions Relating to Hay Fever," published in the *MEDICAL RECORD* in October, 1876, and to the *American Journal of Inebriety* for 1876 and 1877, for papers on inebriety as a disease, by Drs. Mason, Parrish, Crothers, and others.

Transient numbness and various abnormal referred sensations—as pricking, stinging, a feeling of localized cold, crawling beneath the skin, and flying neuralgia—oftentimes drives a patient to the doctor, or to silent despair, lest paralysis be at hand. There is much of unscientific fear in this regard. Many of the premonitory symptoms of locomotor-ataxy—as flying, boring neuralgic pains, abnormal sensations at the bottom of the feet, pain in the back, and so forth—may be perfectly simulated by functional trouble of the cord. The confounding of organic and functional disease has been unintentionally encouraged by certain German writers who have neglected to make proper distinction between spinal irritation, spinal congestion, and spinal sclerosis. This neglect is the effect, in part, of the lack of opportunity in Germany of studying spinal irritation and the class of diseases to which it belongs.

The following case illustrates at once the importance and difficulty of making the differential diagnosis between organic and functional nervous disease.

V.—HYSTERIA AND PARALYSIS FOLLOWING SPINAL CONGESTION—RECOVERY UNDER GENERAL FARADIZATION ALTERNATED WITH CENTRAL GALVANIZATION—RELAPSE UNDER EXCITING CAUSES.†

Miss C. P., a maiden lady under middle life, consulted me in June, 1874, for symptoms of paralysis of the lower limbs. She could not walk across the room, even with crutches, and was forced to get about by means of a machine such as is sometimes used for children with infantile paralysis.

The origin of the difficulty was by her referred to taking cold while sitting on a cold stone on a mountain-climbing expedition at the time of the menses. An immense variety of symptoms, primary and secondary, followed that exposure—among others, ulceration of the uterine. At one time there had been general and severe hyperæsthesia; the sensitiveness had been so great that a slight touch was disagreeable. Various other hysterical symptoms also appeared.

She had been treated by general faradization before I saw her, and for a long time with a certain degree of benefit; but there remained a paralysis of the lower limbs, with frequent attacks of pain in the back and sides, and various evidences of nervous sensitiveness and debility. Insomnia was an unpleasant symptom.

I began treatment by central galvanization. The first application was quickly followed by sound sleep. Being thoroughly persuaded that the symptoms were mainly of an hysterical character, although excited originally by exposure to cold, and although there had been proofs of spinal congestion, I continued the use of central galvanization, with surprisingly rapid results. In one week she could walk with a cane, and the machine was cast aside. The improvement went on with various fluctuations, until in two months she was able to walk, with assistance, in and about the house. The various functions improved at the same time with the power of locomotion, and in a few weeks the patient was able to go about independently. She then left the city, but she informs me by letter that from that time to the present her health has in various respects been very much better; long after the special treatment was discontinued the improvement progressed steadily. Early in the autumn, however, she was persuaded to take sea-bathing, which brought on a return of many of her symptoms. The following summer she again improved to such an extent that she was able to do housework. The following winter she had an attack of diphtheria,

which exhausted the system and caused another relapse. This present season (1877) she is again as well as usual.

The spinal cord, when once it has been exhausted, very readily relapses under exciting causes. It is somewhat hazardous to report a case as permanently cured and out of danger because nearly all the symptoms have disappeared. I knew a lady with symptoms in many respects similar to those in the case just detailed, who, after a long course of electrical treatment, had substantially recovered, to her great satisfaction. One day she chanced to fall down. The shock put her back for months, although she again recovered under the same treatment.

#### VI.—SPINAL IRRITATION IN A MALE.

A young married man, about thirty years of age, had been for over a year afflicted with spinal irritation, accompanied, as usual, with considerable debility and insomnia. The spinal tenderness was noticed chiefly in the middle dorsal and lumbar vertebrae; very little usually at other points. The patient attributed his difficulty to over-physical and mental toil in his business.

Unless the spine had been examined, the condition of spinal irritation might not have been suspected; the patient would have been described simply as "run down," or "debilitated;" no special attention would have been given to the spine, and only general tonic treatment would have been used. The employment of general tonic treatment would have been perfectly proper; indeed, it was used in the present case, but it was aided throughout by local treatment—the use of small blisters and spinal galvanization. Internally, the use of the preparations of phosphorus and zinc certainly aided in the ultimate recovery, after electrical treatment was abandoned.

One of the most prominent symptoms in this case was inability to walk or to ride any considerable distance without general fatigue and pain in the back. This symptom would not point to the spine necessarily, to one not accustomed to examine the spine in nervous affections. The case is one of many that illustrate the importance of making routine examinations of the spine, just as we make routine examinations of the retina or urine in chronic disease, or of the tongue and pulse in acute disease. *When we find spinal tenderness associated with other symptoms and history that exclude all organic or inflammatory disease, or permanent congestion of the cord, or of its membranes, or of the vertebra, then we have spinal irritation.*

The accompanying symptoms vary indefinitely with the locality of the irritation. Irritation of the upper cervical vertebrae may be accompanied by pain in the nape of the neck, by cerebral irritation, with tenderness all over the scalp, or at certain points, or on the vertex only; and there may be also stiffness of the neck, making it difficult or impossible to turn the head, suggesting rheumatism, and usually diagnosed as rheumatism, since the superficial resemblance is very close. Irritation of the middle dorsal vertebrae—the most common form—is accompanied by pain, feeling of pressure on the chest, and flying neuralgia, and numbness of the arms. Irritation of the lower dorsal vertebrae—a less common form—is accompanied by gastralgia, dyspepsia, intercostal neuralgia, and sometimes by palpitation of the heart. Irritation of the lumbar vertebrae—a very common form—is accompanied by flatulence, constipation, sexual disturbance, and flying neuralgia and numbness and paralysis of the lower limbs, peculiar sensations

at the bottom of the feet, and sometimes tenderness of the bones. Coldness of the limbs and muscular twitchings may accompany all forms of spinal irritation. Another common symptom is readiness of the limbs to fall asleep on slight pressure, as in sitting or riding.

The probability that spinal tenderness means simply spinal irritation, and not an organic or permanent inflammatory condition of the cord, or of its membranes, or of the vertebrae, is increased by all evidences of a nervous diathesis, and is made certain when the necessary evidences of organic or permanent inflammatory disease are wanting. That temporary hyperæmia of the cord or of its membranes may occur in spinal irritation is more than probable, and it is not unlikely that under exciting causes the hyperæmia may extend the entire length of the cord; but such hyperæmia is not the disease, but one of the *results* of the disease—of the exhaustion of the cord, or myelasthenia—and this transient hyperæmia may appear and disappear every few hours or days. One day you may examine the spine and find tenderness at certain points; the next day there is no sign of it. This phenomenon does not appear in organic or permanent inflammatory disease.

We can approach this much-discussed subject through the door of analogy. A good analogue is cerebral irritation. In this condition the whole scalp, or only parts of it, may be tender. Does any one suppose that the membranes of the brain are inflamed in such a condition, or that there is any local hyperæmia or anæmia underneath the tender points that will in a pathological sense account for them?

Another good analogue are the tender points in neuralgia. What is the pathology of those tender points that come and go like the clouds of summer? Can it be anything more than nutrition-disturbance, of which almost any temporary circulatory irregularity is one of the results?

In considering this subject it must be remembered also that in spinal irritation the tenderness is by no means always confined to the spine. The whole back may be tender; the scapula and bones of the pelvis may be tender at points; there may be tenderness of the head of the hip-bone, of the clavicle, and of bony prominences everywhere. These tender points must have a common pathology—exhaustion, mal-nutrition, or irritation, as we may choose to term it. Ultimately analyzed, this disturbance is probably of a molecular character, or, at least, beyond the reach of the senses, even with all the aids of modern research. The disease is not on that account any the less a reality, or less worthy of study, for the senses introduce us to but a fraction of nature. A very large number of cases in society that are variously and vaguely described as debilitated, overworked, run down, and so forth, are really cases of spinal irritation. They are, it is true, generally debilitated, or neurasthenic, and anæmic; but the cord is the chief seat of their debility, and if special attention is given to that organ, and rest instead of severe labor is enjoined, the chances for recovery are far greater than under indiscriminate tonic treatment.

In regard to the group of diseases treated of in this series of papers, various queries have been raised of great scientific and practical importance. A few of these I will here briefly answer:

*First.*—Why are these diseases more frequent in the northern and eastern parts of the United States than in any other part of the world?

The fact, for those who have examined all sides of the subject, must be allowed without question.

Extremes of heat and cold, and dryness of atmosphere, are probably the chief factors in the explana-

tion. No other great and highly civilized country enjoys such extremes of climate as the citizens of New England and the Middle and Western States. The Englishman's complaint, "Half the year we freeze, half the year we roast," is quite just; our climate combines the tropics and the poles. This alternation of extreme heat and extreme cold has primarily a stimulating, and secondarily an exhausting influence, as is shown in various ways. One of the most powerful local stimulants is an alternate application of ice and hot water. The American constitution is kept under the almost constant influence of such stimulation. The excessive stimulation is further heightened by the dryness of the atmosphere, and not unlikely by attendant electrical conditions of a peculiar character.\*

That it is not heat alone that induces our nervousness is proved by the fact that, as we go south, nervousness diminishes. None of the diseases described in this series of papers are as common north of Mason and Dixon's line as south of it, although they exist, more or less, in every State. This I have proved statistically of hay fever; and observation and much inquiry of physicians teach me that it is equally true of all the other-diseases of this group, hay fever in this respect being only a type of all. Hence it is that nervous patients, even more than consumptives, are benefited by a trip or residence South. Hence it is that coffee and stimulants are better borne, and can be and are used with far greater freedom South than North.

The climate of California, although it possesses in different parts many varieties, is, on the whole, equable, one month being on the average much like every other month; and in spite of the speculation and other excitements of that new country, and the very unusual dryness of the air in certain districts of the Pacific Coast at certain seasons, there is, so far as I learn, less nervousness than in the East, and although the thermometer frequently goes above 100° in the shade, sun-stroke until last year has been but rarely experienced. Hay fever, likewise, is exceedingly rare in California, although it exists and may sometimes be indigenous in that State.

*Second.*—Why are these diseases more frequent in females than males?

The general fact that females are greater sufferers from hysteria, neurasthenia, and kindred disorders than males, is undeniable; and yet they are sufficiently common in males, and oftentimes more obstinate in them. Inebriety and hay fever affect men more than women, because men are more exposed to the exciting causes; but, to nearly all the other affections here referred to, women are far more liable than men, and mainly as it would appear for these four reasons. (1). They are of a finer organization. (2). They have psychologically less will and more emotion. (3). Their pursuits are more confining and restrictive, and make less demand on the intellectual qualities. (4). Their generative apparatus is more complex than that of man, and constitutes a larger and more exacting fraction of the system.

Deficiency of will alone accounts for much of the nervousness of women; their psychology is against them. Our method of female education and social life also tends to develop emotion rather than the higher qualities of intellect, although in this respect there is constant improvement.

*Third.*—What will be the future of these diseases in this country?

Will this increase, so marked during the past half-century, go on indefinitely? Probably not, at least to the same degree. It is the tendency of evil to work its own cure. Various causes are now operating to retard this increase of nervousness in the American people. We live much better than formerly; have better food, in larger and more nutritious variety; dress more comfortably; take far more recreation, and are less under the influence of theological terrorism. Then there is growing up here quite a large class of hereditarily rich citizens, who, being above the need of toil and strife and anxiety for bread and beef, can keep their forces in reserve for their own physical welfare, and for that of their children. This leisure class, on its best side, is one of the safeguards of the nation's health. The increasing smallness of families, of which Dr. Nathan Allen has written so much and so justly, has this compensation, that it gives those who are born a better chance in the fight for life. All these factors working together have already told beneficially during the last quarter of a century on the American people; we are certainly increasing in weight, and improving in form and comeliness. The American men and women were never before so healthy and handsome as to-day. One of the special signs of this improvement is the decrease of nervous dyspepsia, once so common and so intractable. Probably other neuroses of this group are also on the decline. I am sure that certain types of asthenopia, partly of a psychical origin, that were so annoying to our colleges and seminaries twenty years ago and more, are not common at the present time. It is not impossible that hay fever and inebriety may soon reach their maximum, and also begin to decline; that longevity among the brain-working classes has increased is now, I suppose, undisputed.

Improved methods of sedative and tonic treatment combine with more rational hygiene to modify this tendency of neuroses to increase; by the use of electricity, massage, and the internal administration of oils and fats, many constitutions shattered and broken down and impoverished through anxiety, application, or excesses, can be, in a measure, renewed, that formerly would have been treated on wrong principles, and have suffered all their days.\* The near and remote offspring of such sufferers must partake of the improvement which their ancestors receive. Quarter of a century ago children suffered on account of the bad medical treatment to which their nervous parents submitted. Those who suffered from any of the diseases in this group in the first half of this century were liable to suffer far more from the treatment than from the disease. In some instances constitutions were broken down permanently through long-continued depleting and exhausting measures. I knew a man who, about fifty years ago, was attacked while in college with nervous dyspepsia; for this offence his physician, a conscientious and good man, shut him up in a dark room and regularly bled him, meanwhile keeping him on starvation diet. A very strong constitution carried the sufferer through, but all his life was enfeebled in consequence. In those days the neurasthenic or nervously exhausted were forced to

\* In Sacramento, California, and vicinity, they have at times a peculiar north wind that sweeps through the valley, and is accompanied by very marked electrical disturbances. Its effect on men, on animals, and on vegetable life, is injurious. A very interesting account of this north wind was published two years ago by a clergyman of Sacramento.

\* In Part I, speaking of the treatment of these neuroses, I omitted mention of one combination that I have been using during the past summer—the phosphated wine (vinum nutritio phosphaticum), prepared by Hunt & Dunlap, druggists, of this city. It consists of fermented grape juice, with the phosphates of potassium, calcium, magnesium and sodium. It is a very palatable preparation, and apparently effective in some cases that will not bear the emulsions, or di-bike to take them.

live low and live poorly; to abstain from fats,\* the very kind of food that they especially needed in such cases, and to take severe and disagreeable muscular exercise. Only a few years ago I knew a man stricken with paralysis, and in a condition of general exhaustion, who was advised to chop wood as a cure. He kept on curing himself by the prescription until he was nearly dead. Inasmuch as everything in the constitution, good and bad, is hereditary, or, at least, subject to the law of inheritance, it is just to infer that those who treat patients in the group of diseases here described by sedatives and tonics and nerve food, will so far forth benefit future generations, and aid perhaps in arresting the increase of these maladies. The degeneracy and decay of teeth is without question one of the results of the increase of nervous sensitiveness. This degeneracy was first observed in this country, and probably for the same reasons that neuroses are most numerous here. The teeth are on the average good barometers of the constitution. Dentists tell me that this degeneracy of teeth of the white population of our country is apparently not yet arrested, and is probably increasing.

In bringing this series of papers to a close, I may say that some of the leading views and facts were brought out in a paper on neurasthenia, a number of years ago, and incidentally also in other writings; but the interest manifested in the subject was so slight that it seemed best to wait for a time before formally returning to it. Since that time, views substantially similar on some points have been expressed by Dr. Jewell, of Chicago, and Dr. Mitchell, of Philadelphia, and other writers.† There is also an increasing number of practitioners who recognize all of these maladies, and who treat them on the principles here indicated, and who, perhaps, may be interested in a comparison of experiences. Hundreds of times during the past few years have I been asked why physicians do not give more attention to hay fever, so that at least they might diagnosticate, if not cure it. The usual reply has been that this malady has, so to speak, sprung upon civilization so suddenly that there has not been time to obtain and also diffuse a knowledge of its nature and treatment; but that in the next generation physicians will understand the symptoms and treatment of hay fever as well as they now understand the symptoms and treatment of chills and fever. What will be true of this one disease will be true—indeed, is already becoming true—of all other diseases belonging to this group.

### THE CABLE SPLINT.

By CHARLES F. STILLMAN, M.D.,

PLAINFIELD, N. J.

(House-Surgeon St. Francis's Hospital, N. Y.)

WHILE treating a fractured acromion process in March, 1877, the inability of any splint then in use to

\* Dr. Brush is my authority for the statement that in a certain part of the town in New Hampshire where he passes his summers, there has been in late years a remarkable increase of consumption. Whole families have been swept away, and their houses are left desolate. The situation of the town is elevated, and in every respect healthful, and formerly consumption was not common there; but recently an academy has been established in the vicinity; a love of dress has been introduced among the natives; also a market for their butter, milk, and eggs, which they dispose of—reserving very little for themselves—in exchange for fineries and furniture. The consequence is that the natives have no fatty food, and are starving themselves to death; at least, such is Dr. Brush's conclusion.

† In France, Charcot and his pupils are investigating certain hysterical affections, with more enthusiasm than has hitherto been bestowed on diseases of this class.

retain the fragments in apposition, led me to devise the apparatus now to be described; and the success attending its application to that fracture, and also to fractures of the clavicle and humerus, has led me to place it before the profession.

The splint is constructed as follows: After approximation of the fragments, the arm is encased to the axilla with plaster-of-Paris bandage in the usual manner, as shown in Fig. 1.

FIG. 1

FIG. 2

The next step consists in passing folds of the same bandage around the chest, covering the side of the shoulder, as in Fig. 2.

A shoulder-cap of good thickness is then formed of strips of the same, bound down by transverse chest bands, as in Fig. 3.

FIG. 3

FIG. 4

Thus far the apparatus does not differ materially from those now in use—the suspension of the arm in a sling usually completing it.

At this stage of the process, the *cable*, which cements the various parts together, is formed.

A roller of plaster bandage from three to five inches in width, and of good length is selected.

This is laid over the shoulder as far back as the spine of the scapula, and brought forward and downward behind the wrist, around which it is wound several times to afford as broad a base as possible, and passed anteriorly back over the shoulder to the starting-point (see Fig. 4), where it is bound down by a turn around the chest, and again brought forward to the front of the wrist, under which it passes.

In returning to the shoulder it is wound tightly around the three slips already passed; thus forming the nucleus of the cable (see Fig. 5).

FIG. 5

FIG. 6

Upon reaching the chest band, the bandage is passed around that until the cable is again reached (see Fig.

6), which is once more wound to the wrist, after passing around which the bandage is returned to the shoulder in the same manner, and again brought around to the cable, which is once more wound as before.

By repeating this winding process a number of times, a plaster cable is produced of great strength and intimately incorporated with all parts of the apparatus, binding and solidifying it in a manner which

prevents all disarrangement of the parts covered (see Fig. 7).

#### ADVANTAGES OF THE CABLE SPLINT.

##### 1st. Perfect immobility.

The cable may be grasped and shaken rudely without giving pain to the patient, or disturbing the relations of the parts beneath.

##### 2d. Ease of application.

3d. It does not constrict the neck, as does the ordinary cloth sling, the weight being borne by the shoulder and upper part of the chest.

4th. It prevents the leverage outward of the arm upon the shoulder, which is not entirely obviated by any other apparatus now in use.

#### USES.

1st. In fractures of the clavicle, scapula, and humerus.

For the first, the shoulder should be held upward and backward during its application.

2d. For insuring rest after dislocation of the elbow or shoulder-joints.

3d. For disease of the elbow or shoulder-joints. For the former the splint is applied as in Fig. 8, and possesses the advantages of securing perfect freedom from motion, and yet leaving the affected joint open for inspection and dressings.

## CASE OF PERINEPHRITIC ABSCESS.

By F. L. FORSYTH, M.D.,

PROVIDENCE, R. I.

*History.*—Patient H—, accustomed to the excessive use of alcohol, broke off from the habit six weeks before coming under medical observation. At that time exposure to wet and cold was followed by sore-throat, substernal tenderness, anorexia, pains of rheumatic character, constipation, and night-sweats.

Family history not known.

Two years ago patient had perineal section performed for strictura urethrae following gonorrhœa; has used no sounds or bougies since that time.

*Present Symptoms.*—October 14, 1876: general

pains, thirst, night-sweating, frothy, white expectoration, and diminished amount of urine, of dark color and high specific gravity. His urine was passed with difficulty, and stream was very small. Crepitant râles were heard over lower left chest, behind, but no dullness could be determined on percussion.

Oct. 15th.—Slight dullness over lower lobe of left lung; bronchial respiration, with no râles; prolonged expiration on right sides; no râles; rusty expectoration; chlorides in urine diminished. Pulse 80; temp. 100°. From Oct. 16th to Oct. 20th the average of the daily pulse was 103, and the temperature 103.4°. Oct. 20th there was developed a slight friction-murmur in the axillary line, at the base of the chest, on both sides. No effusion was present; neither did any occur subsequently. Patient has been growing gradually weaker. The lungs have returned to their normal condition.

Oct. 21st.—Pulse and temperature normal. Oct. 22d.—Delirium and great pain. Oct. 23d.—More comfortable; pulse and temperature normal.

Oct. 25th.—Complains of pain in left side, below the false ribs; pulse and temperature slightly elevated. Pain increased until Nov. 9th, when patient had a profuse diarrhœa, which was not controlled till Nov. 14th.

Nov. 12th.—Temp. 101.5.

Nov. 13th.—Temp. 102.5.

Nov. 14th.—Pain in side more severe. Patient also complains of pain near external abdominal ring, but no visible cause was found, nor was there tenderness on manipulation. Temp. 104°. In the afternoon there was circumscribed redness, with fluctuation opposite last dorsal vertebra. Obtained, by aspirating, four ounces of laudable pus. Evening: pulse 88; temp. 101°.

Nov. 15th.—Pulse 80; temp. 100°. Patient stronger, but no appetite.

Nov. 16th.—More pain. Aspirated and obtained six ounces of pus.

Nov. 20th.—Four ounces of pus obtained by aspiration.

Nov. 22d.—Six ounces of pus, and

Dec. 1st.—Four ounces of pus by same means.

Dec. 2d.—There is a small opening where abscess was aspirated, and a continual leaking of pus.

Dec. 19th.—Made free incision into abscess; some pus discharged. Probe passed in four and a half or five inches. Oakum tent was placed in the opening, and the discharge continued till Jan. 2d, and at this time, the tents having been removed, the opening healed.

Jan. 15th.—Small sounds were passed, after which patient passed from 2,400 c.c. to 3,250 c.c. of urine *per diem*; sp. gr. 1013; no albumen or sugar.

Feb. 17th.—Patient's health being in good condition, divulsion of urethra, according to Holt's method, was performed. 3,000 c.c. of urine *per diem* still continued to be passed for a week, then diminished, and March 1st the patient was apparently in perfect health.

The patient had not at any time received an injury in the region of the kidney, but, as in the cases reported by Dr. Bowditch, he was very much debilitated when the disease commenced.

The urine at no time contained albumen, blood, or pus, and the retention was due to the stricture.

The troublesome diarrhœa which he had Nov. 9th seemed to be caused by extension of the inflammation to a portion of the intestines.

The patient at first was treated simply for the pneumonitis. Stimulants were pretty freely demanded both at that time and subsequently. After the subsi-

dence of the pneumonitis, the patient, besides having his appetite tempted in every way, took quinia and cod-liver oil.

Iodine and mustard were employed as counter-irritants at the time he complained of pain.

The infrequency of the affection is my apology for presenting the case.

PROVIDENCE, R. I., May, 1877.

### A CASE OF VOMITING IN PREGNANCY SUCCESSFULLY TREATED WITH INGLUVIN (VENTRICULUS CALLOSUS GALINACEUS).

By CHARLES G. FROWERT, M.D.,

PHILADELPHIA, PA.

I WAS called to see Mrs. S., aged 27 years, June 8, 1877, who stated that she was suffering from constant and excessive nausea, which was only relieved upon assuming the recumbent posture. This continued, gradually increasing from day to day, until in a week it eventuated in retching and emesis, during which watery matter with an acid taste, followed by bile, was ejected. This reached such an extent that the patient had hardly any freedom from it during the whole twenty-four hours, vomiting as often as twelve times a day.

Taking this in connection with suppression of the menses, I concluded she was pregnant, and obtained from her the following history:

This was her third pregnancy. With the two preceding ones she suffered quite as much as with this, and, according to her statement, "had employed the services of several physicians, who administered almost every medicine in the pharmacopœia," but without avail, and she was obliged to lie in bed almost the entire nine months, in order to obtain relief from vomiting.

I proceeded to treat her in the orthodox way; advised the administration of a gentle cathartic, gave carbonic-acid water freely, and prescribed the following:

R  
Bismuthi submit. . . . . ℥ j.  
Pepsine sacch. . . . . ℥ ss.  
Cerii oxalat. . . . . gr. ix.

M. In chart. No. vj. Div. et sig. one every two hours in carbonic-acid water.

This was not followed by the slightest remission in the symptoms.

I then doubled the quantity in each powder; this also failed.

I finally increased the subnitrate of bismuth to ℥ i. doses every three hours, as recommended by several eminent physicians. This was followed by acid, hydrocyanic, dil., two drops every three hours, also highly spoken of. Various hygienic measures, as well as some other medicines, were resorted to, but all failed to bring about the desired relief.

About this time my attention was called to the preparation *inglavin*, recommended in cases of this kind, and I determined to try it at once.

I prescribed *five grains* of Warner's *inglavin* every two hours, and continued this for three or four days, without any appreciable result other than diminishing the violence of the attacks of retching and vomiting.

Increased the dose to *ten grains* every two hours. This seemed to relieve my patient to such an extent that she only vomited before meals, at the sight or smell of food.

I then increased the dose to fifteen grains, giving it half an hour before each meal. This soon had the desired effect of controlling the attacks. Continuing the same dose every three hours, the vomiting and nausea ceased entirely in four or five days.

She made a complete recovery in the second month of her pregnancy, in three weeks from the time she commenced the use of *inglavin*.

*Inglavin* has certainly proved very efficacious in my hands, and I would therefore cordially recommend it to the medical profession as worthy of a trial. I consider it an invaluable remedy in obstinate cases of vomiting in pregnancy.

I might also add that I have used *inglavin* successfully in several cases of chronic dyspepsia, in which pepsin had failed.

## Progress of Medical Science.

INTERNAL USE OF OPIUM IN THE PHOTOPHOBIA OF SCROFULOUS CHILDREN.—Dr. Betz states that opium given internally relieves the photophobia in cases of phlyctenular keratitis in children much more quickly and thoroughly than the local use of atropine. He gives five or six drops of the simple tincture, at bedtime, to children of two or three years. At the same time he uses cold compresses, or, if the case be severe, iced compresses, but regards the tincture of opium as his chief remedy. He gives this in gradually increasing doses, until a quiet sleep is produced, and then stops. The opium not only controls the restlessness and jactitation during sleep, but also causes a rapid melioration of the local symptoms. The patients are able to open their eyes earlier than usual in the morning, and sometimes the action of the opium is so prompt that the photophobia completely disappears after two or three days of treatment. Not infrequently local treatment is unnecessary, as the phlyctenula is usually of little importance. The disappearance of the photophobia is attended by a change in character, the previously sulky, peevish children becoming cheerful and happy. To prevent relapses, Dr. Betz continues the evening use of opium in diminished doses for some time, and believes that its use improves the entire nutrition of the children. The temporary constipation caused by the opium is of little importance, and laxatives should be used with caution for fear of weakening the patients and interfering with the action of the opium.—*Memorabilien*, 22d Year, 7.

DEATH FOLLOWING AN INJECTION OF APOMORPHIA.—At the meeting of the *Niederrheinische Gesellschaft*, in Bonn, on Dec. 18, 1876, Dr. Ungar reported a case of sudden death following the subcutaneous injection of one-fifteenth of a grain of muriate of apomorphia. The patient was fifty-four years old, of kyphoscoliotic build, and was suffering from chronic bronchial catarrh, and moderate emphysema. The prognosis *ad vitam* was not unfavorable. The apomorphia was injected in the neighborhood of the ensiform cartilage, and seven minutes later the patient died with symptoms of collapse. There was no vomiting. The autopsy, which was made by Prof. Koester, revealed nothing that could explain this sudden death.—*Memorabilien*, 22d Year, 7.

RESECTION OF THE KNEE-JOINT WITH CROSS-SECTION OF THE PATELLA.—During the last three years, Prof. R. Volkmann, of Halle, has performed resection of

the knee-joint twenty-one times, with the loss of only one patient, who died of acute basilar meningitis, three weeks after the operation. In all of these cases, nevertheless, the operation was a particularly severe one, for in all of them it was considered advisable to extirpate the capsule *in toto*. In the more favorable cases the wound healed completely and permanently, without any fistula or drainage openings, in from sixteen to twenty-one days, and even in the most unpromising cases the process of cicatrization was, as a rule, considerably shorter than is usual. Prof. Volkmann now combines extirpation of the capsule with resection of the bones in all the joints whenever there is marked fungous degeneration of the capsule or pronounced tuberculosis of the joint. After resection of the hip-joint he has repeatedly seen the wound permanently closed at the expiration of six or eight days, and three weeks after the operation some of the patients were able to walk about with the Wolf-Taylor apparatus, and to leave the hospital. In all his cases the strict antiseptic treatment was employed.

For the total extirpation of the capsule a somewhat larger incision of the soft parts is required than would otherwise be necessary. The usual longitudinal incision, however, answers well enough for the shoulder-, elbow-, and hip-joints. For the knee-joint Langenbeck's longitudinal, arched incision is better than the H-shaped or the curved incision across the joint, because it leaves the quadriceps extensor tendon intact, but it does not give sufficiently free access to the joint. To secure both the advantages, Prof. Volkmann proposes to make a horizontal incision across the joint, and to divide the patella with a saw into two halves, which are to be united by catgut sutures at the end of the operation. He has already operated four times by this method, and in all four cases the wounds healed by first intention, and the two halves of the patella have united so perfectly that no furrow or ridge can be discovered by palpation. He found that this plan gave him freer access to the joint than could be obtained by any other method, while at the same time the incision was not as extensive as the longitudinal or U-shaped incision. In one case the patella was perfectly firm fourteen days after the operation.

The incision extends horizontally across the patella from the anterior border of the epicondyle on one side to the anterior border of the epicondyle on the other side. The joint is opened on both sides of the patella and the index-finger passed under the bone, which is then divided with the saw or knife. The lower half of the patella is now drawn downwards and secured out of the way, while the lateral and crucial ligaments are divided and the end of the femur resected. The head of the tibia is next pressed forward into the wound, and the semilunar cartilages are seized at their posterior borders and removed along with the remains of the crucial ligaments, and the greater part of the adipose tissue which covers the posterior surface of the ligamentum patellæ. The head of the tibia is then laid bare and resected, the capsule is dissected out, and any carious spots in the resected bones or in the patella are gouged out. Finally the resected surfaces of the femur and tibia are brought together by two strong catgut sutures placed laterally, and the two halves of the patella are united also by two catgut sutures. The sutures are introduced into both the epiphyses and the patella by means of strong curved needles. The operation should always be preceded by an exploratory incision, which will enable the surgeon to examine the joint by both finger and eye; for this purpose the incision

should at first only be carried from the epicondyle as far as the border of the patella. If this explanatory incision shows that the operation can possibly be avoided, a drainage tube should be introduced and the wound dressed antiseptically. The patella will sometimes be found firmly attached to the femur, but it can be easily separated with the chisel.—*Deutsche Medicinische Wochenschrift*, August 18th.

EXOPHTHALMIC GOITRE CURED BY GALVANIZATION OF THE SYMPATHETIC IN THE NECK.—The *Gazette Medicale* of Sept. 1 quotes the following case from the *Giornale Veneto di Scienze Mediche*: The patient was a girl nineteen years of age; her brother suffered from progressive muscular atrophy, his sister from frequent attacks of hemicrania, and she herself had been subject, throughout youth, to repeated diarrhoeas accompanied by colicky pains, which occurred without traceable cause, and proved rebellious to all treatment.

Two years ago the eyes became more prominent, and palpitation of the heart appeared. Shortly afterwards a tumefaction of the neck was noticed, accompanied by emaciation, prostration, frequent flushing of the countenance, diarrhoea, and change of character, which became irritable and capricious; the digestive functions became languid. Dr. Ancona proposed galvanization of the first cervical ganglion of the sympathetic. The poles were applied to either side of the neck behind the angle of the jaw, pressing back the sterno-mastoid muscles. He employed at first ten elements of the apparatus of Dr. Stoehrer. Each application lasted from three to five minutes. After a few days the circuit was frequently interrupted.

The physiological effects observed were: Dilatation of the pupils at each closing of the circuit, more marked on the side corresponding to the negative pole; slight contractions of the sterno-mastoid muscles; sometimes an increased flow of saliva, and a coppery taste in the mouth; occasionally some vertigo. In the course of five months, one hundred sittings were had. The treatment was well borne, and during the whole time she only suffered from one severe attack of hemicrania, and two very light ones. With the treatment by electricity was associated the internal administration of arsenic. From the very beginning of the treatment a notable amelioration was observed which proved continuous, so that at the end of five months the patient had increased in weight some 13.5 kil. (about thirty pounds). The face and the mucous membranes gradually returned to their normal color. The eyeballs regained their position and their mobility; the thyroid body became greatly diminished in size; the pulsation of the arteries ceased to be visible; the cardiac impulse became regular; the pulse beat forty times a minute; menstruation became regular, and with the digestive functions the strength returned.

JAPANESE PRACTICE.—It is said that the Japanese have such a high estimation of the value of the services of an educated physician that they think it an insult to him to offer any other recompense than profuse compliments to his learning, skill, and charity. If such physicians do not become dignified in their calling it is not because they have not plenty of opportunities.

GASTRIC JUICE.—According to the recent experiments of M. Laborde, (*Société de Biologie*, June 9th.) free hydrochloric acid does not exist in the gastric juice in the physiological state.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, October 20, 1877.

## HOW TO MAINTAIN DISCIPLINE.

THE necessity for a Code to govern our professional conduct is in itself a reflection upon our character as liberal, high-minded, and honorable gentlemen. But while it may be said that the upright man needs no set of rules to guide his course or regulate his relations to his peers, there are enough men in our ranks whose moral obliquity make them the fit subjects of discipline. It is the enforcement of the latter which is always disagreeable and sometimes difficult.

With the knowledge that no one is perfect either in motive or in act, it is always an ungracious task to make charges against a brother. Rather than become a prosecutor on behalf of the profession, almost any medical man would smother his individual indignation and keep quiet. Yet every one knows that this is not the way to uphold the dignity of our calling, to respect our laws, or to protect our personal rights. If we have a Code to which we subscribe, we are in honor bound to obey its injunctions; and if there are any doubts as to the manner in which we should do it, the sooner they are settled the better. There should be some tribunal before which doubtful cases should be brought. We believe we speak the sentiment of the profession when we claim that the present is a peculiarly fitting time to settle the differences of opinion regarding what should and what should not be considered violations of the Code.

Since the time that a late President of the American Medical Association declared that the Code was virtually useless, and since he rather defiantly accorded his practice with his principles, the whole country has been more or less afflicted with an epidemic of quackery, and even the best of men yield themselves to the temptations of the hour. The consequence of this is a great and growing dissatisfaction among the more conscientious members of the profession. Indeed this is no more than could have been expected.

It is not our purpose to refer to the many open violations of the Code which are constantly transpiring, but to discuss the practicability of enforcing that discipline which shall insure equal rights to all. Obviously the County Societies are the authoritative bodies to which we should appeal. But as they are to act in the capacities of a jury, it is quite important that some one should bring the requisite charges before them. Take, for instance, the Comitia Minora of our own County Society, which may be considered the type of others throughout the country. That Committee is not competent to take the initiative in any case of violation of the Code, but can act only when definite charges are made by other parties. In not attempting to make suitable provisions to meet emergencies, many excellent organizations have crippled their real powers and destroyed their influence for good. As we have before intimated, no single individual, who is not specially wronged, cares to go out of his way to perform what at all times is a very unpleasant duty. Consequently it is seldom or never done, and the violators of the law grow bolder and bolder. To overcome the difficulty in question, there seems to be one remedy, and that is the establishment of a Committee of Ethics, to whom all questions can be referred either by individuals or even by the Comitia Minora itself, and by whom all cases worthy of notice could be brought to the attention of the said Comitia Minora, and by the latter directly to the Society. This would take away the responsibility from any individual, and the duties would be nothing more than purely official ones.

We believe that there is such a machinery in almost all the County Societies save our own; at least if we are mistaken in this latter point, we have no facts to help us to a different conclusion. If there be a Committee on Ethics, it is more in name than in substance. Whichever may be the case, we should like to see it get to work, as in this city there are very many cases which boldly if not defiantly invite attention. In this respect we are not exceptional, for in all large cities such committees can find plenty to do. It is not necessary to say that every little case of supposed wrong-doing should be brought to the notice of the jury, but only the notorious ones.

We think we have arrived at a point when certain things should be decided, that the profession may know where it stands. If it be right for men to advertise operations, to publish circulars in the daily papers, to allow their medical certificates to appear in the public prints, and do many other objectionable things, it is time that the general profession should know it, that they may do likewise. What is fair for Prof. A. or B., is equally fair for Dr. C. or D. If, practically speaking, there must be no Code except for such as must be kept under, we should abolish it altogether and all become quacks at once. Then, in the race for newspaper notoriety, the only anxiety would

be concerning the chances of being overtaken as the hindermost.

The profession is really more interested in settling some of these questions than they are in punishing the wrong-doers. Before some of our leading men began to advertise, the Code was pretty well understood; now, however, the new doctrine calls for some new explanation from our County Societies. We believe if these organizations would do their duties in the premises, which, in the way we have suggested, is quite easy, every respectable medical man would consider it a violation of his obligations to his brethren to appear in the daily prints in any professional manner whatever.

#### THE COLOR-LINE IN MEDICINE.

THE decision of the Faculty of the College of Physicians and Surgeons, denying a student of color admission to lectures, has given rise to much comment. It was certainly unfortunate for the college that a practical solution of this question should be demanded at her hands. Her best friends, doubtless, had confidence in her ability and readiness to meet the issue fairly, and to decide accordingly. Her signal failure, however, in doing so, must be a matter of disappointment if not of astonishment to all. In view of the facts of the case, it is impossible to resist the conviction that principle was sacrificed to policy. It did not seem to be so much the question whether or no the negro should attend lectures, and be taught as his white brethren, but whether his presence would be objectionable in the lecture-room. Although no such issue was submitted to the medical class, the fear of unpleasant results was sufficient to make the professors hesitate to try the experiment. The college, although a public institution, is managed altogether by private enterprise, and all matters bearing upon its financial success are entirely under the control of the faculty and of the trustees. To make the school pay is one of very vital interest to all parties more or less dependent upon its revenue, and hence the supposed wishes of patrons have to be considered. This is a poor excuse, but it is the best which the faculty can apparently offer for the course pursued. Although from the pecuniary point of view the conclusion may have seemed inevitable, those interested in the welfare of the college will nevertheless regret she was not willing to vindicate a principle regardless of consequences. That the proper initiative was not taken is a reflection on her want of independence, and is one of the many arguments in favor of endowment. If the school were endowed, there would have been no hesitation in admitting to its privileges any man, white or black, provided he had the requisite mental qualifications.

It seems too bad that on such trivial grounds of objection so fine an opportunity was not seized for rising above ordinary prejudices, and anticipating what

at no distant day must be inevitable. If there is any test which should cause color, race, or sex to be wholly disregarded, it is intellectual and scientific culture. And yet an educational institution, which, above all others, should verify this test, draws the color-line, and virtually says to the negro, because you are black you must stand aside. Under all the circumstances of the case, even of those which might be qualified by temporary expediency, we believe that the college has committed a grave blunder, of which it will repent at no distant day.

If, in consequence of establishing the proper precedent, there should be any probability of the college being overcrowded with negroes, there would be time enough to act when the emergency arose. In fact, the school could afford to run almost any risk rather than play with the fire which makes the negro a martyr.

#### MEDICAL REPRESENTATION IN THE SCHOOL-BOARD.

As the time approaches for the creation of vacancies in the Board of Education, we take an opportunity to urge the necessity of medical representation. Aside from the fact that our profession is a learned one, ranking in general standing and influence with any other, and consequently capable of advising in general matters connected with education, there is a special reason why its services upon the central board should be required. The intimate relation which has been shown to exist between the physical and mental wants of scholars is such as to place the question beyond the pale of argument, and convince every unprejudiced person of the necessity of the measure so often advocated by us. While there are two very good reasons why the profession should be represented in the way suggested, there is no possible argument against the measure. The Mayor of Brooklyn recognized its utility by appointing Dr. A. N. Bell as a member of the board of that city. The Mayor of our own city cannot go amiss in following the example.

A SALUTARY EXAMPLE.—In France, a pharmacist who does not follow to the letter the directions of the physician in compounding a prescription, and who replaces any of the drugs ordered by others, is liable to prosecution. An apothecary in Lille was recently surprised by the inspectors in the act of putting up a prescription which called for the milk of phosphate of lime, and bitter orange-peel. As he did not have either of these articles in his store, he replaced them by cod-liver oil, quinine, and anti-scorfulous syrup. The Court condemned him to pay a fine of 50 francs, and ordered that the judgment be published in three papers.

A TERRIBLE famine is now desolating the north of China and the Chorea, and the inhabitants are dying by thousands. The famine is principally due to a host of grasshoppers which has ravaged the plantations for 200 miles inland, and the plague has come to aggravate the existing horrors.

## Reviews and Notices of Books.

### TRANSACTIONS OF THE CONNECTICUT MEDICAL SOCIETY FOR 1877. EIGHTY-SIXTH ANNUAL CONVENTION.

THE proceedings of the eighty-sixth annual convention of the Connecticut Medical Society, held at Hartford in the latter part of May last, have just been published in pamphlet form, and copies will be largely welcomed by practitioners on account of the full reports of curious and important cases which the committee on publication have thought best to incorporate. The address of Dr. Burrows, of Hartford, President of the Society, "on Malarial Fever in New England," which figures as the initial document in the report, although purporting to give merely a cursory glance at the subject, is so crowded with facts as to resist clever summary. While amply discussing the history of malarial fever in Connecticut, it furnishes pretty full statistics of the recent epidemic prevalence in several counties of the State. It appears from Dr. Burrows' paper that New Haven and its vicinity formed the centre from which, from 1866 to 1872, the disease radiated, gradually involving Fair Haven, East Haven, Branford and North Branford, Guilford, North Haven, Hamden and Meriden, all of which were visited with considerable severity during the six years specified. In 1872 it had travelled up the Connecticut River as far as Hartford, where it broke out on Wethersfield avenue, one of the exciting and local causes of the outbreak appearing to have been the construction of a sewer about a mile and a half in length parallel with the avenue, through a low marshy ground, underlaid with red clay that lies contiguous, and is partially drained by a sluggish rivulet that empties into Folly Brook. During the summer also—the outbreak occurred in the fall of 1872—the adjacent meadowlands on the east were disturbed by operations consequent upon the construction of the Connecticut Valley Railway. The disease appeared in East Hartford in 1872, but did not become epidemic until the summer of 1876, the terrible heat and dryness of which will be long remembered by weather prophets. The thermometer registered over 90 for thirty successive days, June 20 to July 20, and on four of those days rose to 100. So sudden and universal was the development of the epidemic that along the river, within half a mile of the causeway northward, out of 174 inhabitants 143 came under treatment for intermittent fever—an extraordinary exhibit certainly for a period so brief, and one that justifies the exhaustive study of malarial disease in Connecticut, which forms the principal feature of the transactions of the society at the last convention. Dr. Burrows leans apparently to a theory that Prof. Charles Hooker was among the first to advance, and one that has been pretty generally adopted by medical men in Connecticut, that a gradual change of diathesis, noticeable principally in an increased efficacy of quinine in cases which were formerly aggravated by it, had been in progress for some years previous to the outbreak of the intermittent, and quotes letters from practitioners in the various cities and towns of the State, expressing the opinion that malaria has impressed a paroxysmal type on all diseases occurring within their practice. The reports of the county societies abound in cases of considerable interest to the active practitioner. Dr. Griswold, of Plantsville, details his experience with nitrite of amyl as a remedy in nervous diseases, and Dr. W. F. Parsons, of En-

field, reports a case of hydrophobia, with very full notes of the symptoms developed during the progress of the disease. There was no autopsy.

### TRANSACTIONS OF THE RHODE ISLAND MEDICAL SOCIETY, 1876-1877. Central Falls, R. I. 1877.

ASIDE from routine, the transactions of the Rhode Island Medical Society for the years 1876-7 contain only a single paper, but that one is of material interest to practical men, being a dissertation on diphtheria, read by Dr. W. E. Anthony at the December quarterly meeting, in which, after giving a brief clinical history of the disease as it has come under his observation, he relates his experience in treating it with the sulpho-carbolate of sodium, a paper upon which was, it will be remembered, read before the society by Dr. C. H. Fisher in December, 1875. Dr. Anthony gives notes of eighteen cases of true diphtheria, occurring in his practice within the months of October, November, and December, 1876, in seventeen of which he used the remedy with satisfactory results. In one case, however, the disease proved fatal within thirty-six hours from the date of invasion. The patient was of naturally delicate constitution, and only three years of age. The sulpho-carbolate of sodium appears to increase the amount of urates and lithates in the urine, and may be given in doses of from one to ten grains, repeated every one, two, three, or four hours, as circumstances may prescribe. Dr. Anthony has given as high as 120 grains in twenty-four hours to a patient only seven years of age. The remedy may, he thinks, be advantageously combined with quinine or carbonate of ammonia. Of course, he cannot forbear a learned reference to the German theory that diphtheria is of bacterial origin.

### SANITARY CONDITION OF LYNN, including a Special Report on Diphtheria. By J. G. PINKHAM, M.D. 1877. Boston.

DR. J. G. PINKHAM'S report on the "Sanitary Condition of Lynn," which is reprinted from the eighth annual report of the State Board of Health, Mass., although it discusses at considerable length the causation of typhoid fever, scarlatina, and consumption, is principally valuable to the practitioner because of an exhaustive and careful inquiry respecting the local causes of the severe outbreak of diphtheria that visited that city last year. The reporter has collected the facts of 518 cases, in which the ratio of fatality was 1 to 4.9, and records 96 additional cases, of which no careful memoranda were taken, making in all 614 cases of diphtheria in one year in a city of 32,600 inhabitants. In this report special reference has been had to the natural conditions under which the disease has prevailed, to the artificial conditions under which it has prevailed, and to its contagiousness; the work of special inspection having been mainly entrusted to Dr. S. W. Clark, who appears to have performed his task with commendable efficiency. Upwards of 80 per cent. of the cases were in the valleys of brooks, or in the vicinity of marshes or bodies of water where the soil is usually more or less damp, and nearly all of them occurred in the outskirts of the city, in districts, that is to say, where no means of artificial drainage have yet been adopted. The comparative elevation above the level of the sea appears to have had no special influence on the disease, except in so far as it is a factor in determining the condition of the soil; but it is noticeable that in several of the sections visited during the year, the subsoil consisted of an almost impervious clay. The month of highest prevalence was October, which is

credited with 23 per cent. (or nearly one-fourth) of the whole 614 cases. The disease declined in August, increased rapidly during the latter part of September, attained its maximum in October, and then gradually sunk again during November and December, so that the January list of cases was only 2 per cent. of the whole number for the year. The reporter notes that October, 1876, was several degrees colder than usual, and marked by prevailing north-west winds, a low rainfall, and a very dry atmosphere, while the November that followed was an extremely wet, foggy, and disagreeable month. Again, April, 1876, was an exceedingly pleasant month, although the fatality of diphtheria was at its maximum. Dr. Pinkham draws from these facts the conclusion that the immediate humidity of the atmosphere is not appreciably influential in determining outbreaks of diphtheria, and that medical inquirers must probe a little deeper for its real causation. Concerning the question, whether the disease is contagious, he observes that physicians in Lynn and the vicinity, almost without exception, take the affirmative view, and details a number of cases in which the disease has manifested all the usual traits of contagious diseases. The report is accompanied with maps illustrating the relation of the disease to the drainage and sewage system of the city.

**THE PHYSICIAN'S SELF-COPYING PRESCRIPTION BOOK AND BLANKS.** By WENDELL A. ANDERSON, M.D., Lacrosse, Wis. Chicago: Hadley Bros. & Co.

This is a pocket-sized blank book, which is arranged with carbon paper, for the purpose of furnishing duplicate copies of prescriptions when written with an ordinary lead-pencil on sized paper. This, we believe, has never been attempted before in any contrivance or arrangement for copying. In writing a prescription, all that is necessary is to place the black paper underneath the sheet written upon, when a perfect copy is furnished upon the sheet below. The former is used for the apothecary, while the copy is preserved by the physician. To those who are in the habit of keeping copies of their prescriptions (and every one should), this little pocket-companion is invaluable in saving time and securing accuracy. By its use the physician can always be assured that, in the hurry of his prescription writing, no mistakes have been made.

**HANDBOOK FOR HOSPITAL VISITORS.** New York: G. P. Putnam's Sons. 1877. 12mo, p. 150.

This little manual is one of the many admirable publications of the State Charities Aid Association, and is, perhaps, the most extensively useful of all. It is rarely that we have had an opportunity of seeing so much good sense concentrated in such a small space. The care of the sick is interesting to all who have anything to do with them, and a work such as this commends itself not only to the hospital visitor, the hospital manager, the hospital physician, or hospital nurse, but to the private medical man, the private nurse, and the watchful mother. The article on hospital building, embodying all the principles of construction, management of air, water supply, drainage, heat, etc., is thoroughly practical in character and intelligible to an ordinary reader. Those parts of the work which will, however, prove most interesting to the physician and the practical nurse, are the chapters on housekeeping and nursing service. The remarks upon the latter deserve the widest possible dissemination.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, Sept. 26, 1877.*

DR. F. V. WHITE, PRESIDENT PRO TEM., IN THE CHAIR.

#### LYMPHATIC GLANDS REMOVED FROM THE NECK.

Dr. A. C. Post presented a mass of diseased lymphatic glands, which was removed on the 25th of September, 1877, from the neck of a boy four years of age. The tumor was first observed a little more than one year ago. At first the increase in size was quite slow, but for several months immediately preceding the operation the mass had increased in size quite rapidly. The tumor was situated upon the left side, beneath the sterno-cleido-mastoid muscle, skirted the great vessels, and, expanding, occupied nearly the entire space from the jaws to the clavicle, and from the trachea to the outer side of the neck. The case was regarded as very formidable, and the mother was accordingly informed that it was a matter of some doubt whether the boy would survive the operation. The tumor was growing rapidly, was encroaching upon some of the respiratory organs, as evidenced by occasional cough and dyspnea, and it was thought to be a question of some urgency that it should be removed.

The operation, although performed under the influence of ether, was very tedious, and lasted for two hours. During its performance the patient received an enema of milk and brandy, and also a hypodermic injection of half a drachm of brandy in the thigh. The respiration and pulse continued good during the whole time, and on the morning of the 26th of September the boy was sitting up in bed, and presented good prospects for a favorable recovery. The mass weighed fourteen and a half ounces.

Dr. FINNELL inquired regarding the number of blood-vessels ligated.

Dr. Post replied that no large vessels were encountered.

He performed the operation in accordance with the plan recommended by the late Dr. Alexander H. Stevens, namely—to cut fairly down upon the tumor, and then, keeping close to its surface, gradually enucleate or tear out the different portions from their investing membrane. In that manner the larger vessels were, in a great measure, avoided.

Dr. BUDDON testified regarding the formidable character of the tumor, and stated his impression was that there would be a very serious hemorrhage; but the manner in which the operation was performed narrowed it down to the smallest possible amount.

The tumor was referred to the Microscopical Committee.

Dr. FINNELL inquired of Dr. Post whether he would cut fairly down upon the surface of the growth in the removal of all tumors.

Dr. Post replied that he should do so only in the removal of non-malignant growths.

Dr. E. C. SEGUIN inquired whether there were present any appearances of marked anemia or leucocythemia.

Dr. Post replied that the boy was very pale, yet his general condition was very good, and he had fair appetite.

Dr. McCrory presented the following report of the Microscopical Committee:

In the specimen presented by Dr. J. Lewis Smith, at the stated meeting on May 9th, the following lesions were found:

*Lungs.*—Fibrinous pleuritic effusion on both sides, more marked on the right; consolidation of lower third of upper lobe of right lung posteriorly; microscopical examination shows the blood-vessels in this spot to be tensely distended with blood, while the air-cells are filled with swollen epithelium and small cells. There are several small extravasations. The bronchi do not contain much secretion. Small spots of collapse scattered through both lungs.

*Heart.*—Pericardium covered by a thick, shaggy fibrinous layer. A few of the muscular fibres are granular. The endocardium presents nothing abnormal.

*Kidneys.*—Are in a condition of parenchymatous degeneration. The epithelium of the convoluted tubules, and more especially of the straight tubules of the cortex, is excessively granular; in many it is impossible to discern the boundaries between the cells. The intertubular tissue has undergone no change.

#### TUMOR ON THE BACK.

DR. T. C. FINNELL, on behalf of Dr. James L. Little, presented a tumor, which was removed at St. Vincent's Hospital, Sept. 26, 1877, and accompanied by the following history:

Mary McManary, *æt* 56; born in Ireland; widow; father and mother died of old age. The patient has enjoyed perfect health until the appearance of a tumor, thirty-seven years ago. The first notice, a small tumor the size of a currant, which grew rapidly, and two years afterwards it had attained the size of two fists, when it was removed by Mr. Rand, of Dublin. The operation was a success, but at the end of twenty years she noticed that another small tumor was growing on her back, a little below the shoulder, which was near the original spot; it did not have any discoloration; it grew rapidly, and in three years had attained very nearly the size of the present tumor. She had it removed by Dr. Schenck, of Flatbush. Three and a half years after the removal of that tumor another reappeared in nearly the same place, which grew very rapidly, and in seven months it was as large as the tumor removed formerly. This also was removed by Dr. Schenck, on Sept. 25, 1876.

About December, 1876, she discovered a small tumor at about the same situation as before, which has grown from that time until it has reached its present size. She has suffered no pain at any time, except that caused by the weight of the tumor, which was found, after its removal, to be six pounds. The tumor, at its base, measured twenty-five and one-half inches in circumference.

DR. FINNELL remarked that the history of the case was very interesting, and that it would be desirable to know what the nature of the growth was; whether it was malignant or non-malignant. The specimen was referred to the Microscopical Committee.

DR. POST remarked that there was one feature of the tumor which made it quite unlike a malignant growth, namely—its smooth surface. Malignant tumors, especially of the carcinomatous variety, commonly involved the surrounding tissues, and did not have well-defined outlines. He suggested that it might be a recurrent tumor, which had no marked tendency to affect the general health.

DR. FINNELL remarked that the tumor seemed to be almost encysted; and that it was easily torn out by the fingers.

There was no enlargement of the axillary glands.

DR. BRIDDON remarked that the clinical history was not such as belonged to carcinoma, but rather to the recurrent-fibroid class of growths.

#### CARCINOMA OF THE ILEO-CÆCAL VALVE, WITH STENOSIS—ACCUMULATION OF FOREIGN SUBSTANCES IN THE ILEUM—CONSTRICTIONS AND MALPOSITION OF THE DESCENDING COLON.

DR. SATTERTHWAITE presented portions of the small and large intestine of a patient who had died at the Presbyterian Hospital, in the service of Dr. Hubbard. The history, which was furnished by the House Physician, Dr. Chambers, was substantially as follows: A. D., 49, married, a native of Virginia, was admitted into the hospital August 13, 1877. Her family was said to be free from hereditary taint. During thirty-five years of married life she had one child; had never at any time suffered from uterine disease, and enjoyed ordinary good health until eighteen months previously, when she began to suffer from pains in her abdomen, associated with vomiting. These attacks passed off to recur again at intervals, and yet she was never confined by them to her bed for more than a few hours, until six months before, when she was laid up five months. Since this time similar attacks have been liable to come on after eating. Occasionally she passed a week without taking solid food, and has lost a great deal of flesh and strength.

The patient, on admission, was found to be anæmic, jaundiced, and very much emaciated. She was complaining of very severe pains in her bowels, and nausea. Bowels were constipated; no solid food, and but little liquid, could be retained by the stomach. Spasms of pain would come on every five or ten minutes, at which time the abdominal walls would present an irregularly nodulated appearance, due to the irregular distention of the small intestines. August 16th, the patient had not improved. August 17th.—After the administration of castor-oil internally, and warm enemata, a small evacuation was obtained; but, the abdominal pains becoming severe, recourse was had to hypodermics of morphia. August 20th.—But little success followed the use of injections, the amount of fecal matter brought away being very small; examination per rectum showed some displacement of the intestines, the exact nature of which could not be determined. September 1st.—The patient improved somewhat for a few days, but now is in the same condition as at first. No action from the bowels except when an injection is used. On consultation it was determined to inject the large intestine to its utmost capacity, for the purpose of distending it so as to rectify obstructions or displacements; but when the attempt was made, only one and a half pints of water could be forced in.

September 5th.—Injections of water having given no relief, and the ordinary enemata of soap-suds and oil failing to act as before, enemata of ox-gall and water (ʒj.—Oj.) were employed. But the patient steadily failing, all medicinal treatment was suspended, and milk and brandy per rectum substituted, under which she improved, and finally has some quite free natural passages from the bowels.

September 10th.—The patient decidedly improved under the brandy and milk; her vomiting stopped for several days, and she had voluntary passages from the bowels, but she is now failing again, gradually growing weaker, and the abdominal pains are returning. Sept. 12th.—The pains have been so severe that she has had to be kept under the influence of morphia continuously. ʒ

September 13th.—The vomiting commenced again last night, the pulse failing, and the extremities becoming cold. At twelve midnight she died.

*Autopsy.*—The body was found much emaciated, and the color of the skin was a yellowish brown, much like that seen in Addison's Disease. No tumor in the abdomen was made out by palpation. On opening the *thoracic cavity* the apex of the right lung was found adherent to the wall of the chest, and there were some adhesions along the axillary line. In the upper lobe of the right was a small cheesy nodule, and around it a circumscribed pneumonia. The apex of the left lung also was adherent to the thoracic wall, and there was a moderate amount of diaphragmatic pleurisy. The *heart* was small and contracted, and there was slight erosion of the aorta. The *spleen* was small. The *kidneys* appeared quite normal, except some suspicious points which had very much the appearance of tubercles.

The *liver* was very small, weighing only two and a half pounds, and contained several deposits, some of which were as small as a millet-seed.

About four inches below the splenic curvature there was a notable displacement of the descending colon, and at that point also the intestine was firmly bound to the wall of the abdomen.

From the curvature, the gut descended in a normal manner for about four inches; then, turning upon itself, ascended one and one-half inches, where it turned at an acute angle, and passed downward; the sigmoid flexure and rectum were normal.

The constriction in the colon was so great at the point where the displacement had occurred, with adhesion to the abdominal parietes, that only the little finger could be passed through the flexed portion, and it was with some difficulty that air could be forced through, and only after prolonged pressure.

At the ileo-cæcal valve, a tumor was found. The ileum for a considerable distance above the valve was distended, its walls were very much thickened, and it was filled with fluid fecal matter, which contained prune, date, orange, and grape seeds. There were twenty-three prune seeds. The mucous membrane was extensively ulcerated; neither Peyer's patches nor the solitary glands, however, were particularly involved, but the ulcers had more of the appearance of the tubercular variety. Their long axis was transverse to the longitudinal axis of the intestine. In some instances, the mucous membrane alone was affected, while in others nothing except the serous coat of the intestine remained.

The tumor at the ileo-cæcal valve was about the size of an English walnut, and the calibre of the valve, although diminished, had not been encroached upon to such an extent but that the little finger could be pushed through it with some difficulty; the passage of foreign bodies like seeds would, however, be attended with great difficulty.

On microscopical examination, the tumor was found to be unmistakably carcinomatous.

The deposits in the liver were also carcinomatous. The mesenteric glands in the neighborhood of the caput coli were enlarged and infiltrated with the same kind of deposit.

Dr. Satterthwaite directed attention to certain points in the case which he regarded as specially interesting.

Tumors of the ileo-cæcal valve were rare, and carcinomatous growths affecting that structure were of the rarest occurrence. It was probable that the lesions in the liver could be correctly explained on the ground that they were secondary to the carcinoma in the

valve. If the primary cancer had been in the liver, in all probability a very much greater amount of carcinomatous deposit would have been present, and the size of the organ increased.

What connection, if any, these lesions had with stricture of the descending colon, it was difficult to say.

The trouble about the colon seems to be the result simply of old peritoneal adhesions, and probably was to be classed among those *kinkings* of the intestine which were produced by slow inflammation that resulted in cicatricial tissue and union with the wall of the abdomen.

Dr. Post suggested that it might be possible the irritation produced by the seeds influenced the localization of the cancerous deposit at the ileo-cæcal valve. External traumatic irritation seemed to be a local cause of cancer, and perhaps those hard substances in the ileum might have been the exciting cause of the disease at the valve rather than elsewhere.

THE PRESIDENT referred to a case in which, at post-mortem, an abscess was found in the right iliac fossa, and a cherry-pit was the foreign body supposed to have had something to do with its formation. Scirrhous of the peritoneum was also present. It was thought at the time the examination was made that the mental condition of the patient was the cause of the malignant disease, but that question was submitted to an expert in pathology, who said that it had nothing whatever to do with the development of the cancer.

DR. FINNELL gave an account of a post-mortem examination made at St. Vincent's Hospital, after which the Society went into executive session.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from Oct. 7, to Oct. 13, 1877.*

STERNBERG, G. M., Major and Surgeon. To proceed to Fort Walla Walla, W. T., and resume his duties as Post Surgeon. S. O. 139, C. S., Dept. of the Columbia.

MCCLELLAN, E., Major and Surgeon. Assigned to duty as Post Surgeon at Fort Lapwai, Idaho T., relieving Surgeon Sternberg. S. O. 139, Dept. of the Columbia, Sept. 26, 1877.

GREENLEAF, C. R., Major and Surgeon. Assigned to duty as Post Surgeon at the post to be established at Helena, Mont. S. O. 136, Dept. of Dakota, Oct. 8, 1877.

BROOKE, J., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon at Camp Howard, near Mount Idaho, Idaho T., relieving Assistant Surgeon Matthews. S. O. 139, C. S., Dept. of the Columbia.

GARDNER, W. H., Captain and Assistant Surgeon. Relieved from duty at Allegheny Arsenal, Pittsburg, Pa., and assigned to duty at Atlanta, Ga. S. O. 232, Div. of the Atlantic, Oct. 6, 1877.

MCLEDERY, H., Captain and Assistant Surgeon. Leave of absence extended fourteen days. S. O. 237, Div. of the Atlantic, Oct. 12, 1877.

CRONKHITE, H. M., Captain and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for an extension of one month. S. O. 109, Dept. of Arizona, Sept. 26, 1877.

LORING, L. Y., Captain and Assistant Surgeon. Granted leave of absence for one month, from Oct. 10,

1877, with permission to apply for five months' extension. S. O. 108, Dept. of Arizona, Sept. 25, 1877.

ELBREY, F. W., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon at the temporary camp to be established at or near Spokane Falls, W. T. S. O. 139, C. S., Dept. of the Columbia.

MATTHEWS, W., Captain and Assistant Surgeon. To accompany Companies B and F, 12th Infy., to Dept. of California. S. O. 138, Dept. of the Columbia, Sept. 25, 1877.

AINSWORTH, F. C., 1st Lieutenant and Assistant Surgeon. When relieved by Assistant Surgeon Worthington, assigned to duty at Fort Whipple, A. T. S. O. 108, C. S., Dept. of Arizona.

WORTHINGTON, J. C., 1st Lieutenant and Assistant Surgeon. Relieved from duty at Fort Whipple, A. T., and assigned to duty as Post Surgeon at Camp Grant, A. T. S. O. 108, C. S., Dept. of Arizona.

ROBINSON, S. Q., 1st Lieutenant and Assistant Surgeon. Assigned to duty as Post Surgeon at the post near Missoula, Mont. S. O. 136, C. S., Dept. of Dakota.

DAVIES, W. B., 1st Lieutenant and Assistant Surgeon. Assigned to duty at Fort A. Lincoln, D. T. S. O. 130, Dept. of Dakota, Sept. 26, 1877.

## Medical Items and News.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending October 13, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
Oct. 6.....	1	25	42	3	4	65	0
" 13.....	1	26	40	2	3	49	0

One case of yellow fever was removed to Quarantine Hospital.

FEMALE EDUCATION.—The Board of Visitors of the University of Wisconsin condemn the system of education in that institution, on the ground that it entails loss of health among the females in their efforts to keep up with their classes and overcome the physical frailties peculiar to their sex. The report concludes: "Education is greatly to be desired, but it is better that the future matrons of the State should be without a university training than that it should be procured at the fearful expense of ruined health; better that the future mothers of the State should be robust, hearty, healthy women, than that, by over-study, they entail upon their descendants the germs of disease. And there is no more certain law than that of heredity. The overwrought nervous system undermines the general health stealthily but certainly, and its evil consequences are prolonged in many cases through life."

CREMATION.—At the meeting of the *Conseil Municipal de Paris*, on July 3d, the discussion of M. Leveillé upon cremation was the order of the day. Article 1 of the project presented by the commission was finally adopted; it is conceived in the following terms:

"It is expedient to open a *concours* in order to ascertain the best process for cremating bodies, or any other process which will attain the same end.

"The process must conform to the following conditions:

"a. It must insure the transformation of the organic materials without the production of any odor, smoke, or deleterious gas.

"b. It must guarantee the identity and the preservation, complete and without admixture, of fixed substances.

"c. It must be expeditious and economical.

"d. It must not present any obstacle to the celebration of the religious ceremonies of any denomination."

The remaining articles of the project were referred to a commission, which is to consult with the Prefect of Police.

ALUMNI ASSOCIATION OF BELLEVUE HOSPITAL MEDICAL COLLEGE.—At a stated meeting of the Alumni Association of Bellevue Hospital Medical College, held at Delmonico's, on the 2d of October, the following officers were elected for the year 1877-78: *President*, John W. Pinkham (class of '66), of Montclair, N. J.; *First Vice-President*, Thomas W. Burchard (class of '72), of New York; *Second Vice-President*, James R. Taylor (class of '74), of New York; *Recording Secretary*, George W. Wells (class of '68), of New York; *Corresponding Secretary*, Edwin D. Morgan, Jr. (class of '70), of New York; *Treasurer*, William H. Katzenbach (class of '71), of New York; *Historian* (a permanent officer), F. A. Castle (class of '66), of New York.

The following *Council* was also appointed, according to a recent amendment of the constitution, to hold office permanently, each class being represented, so far as possible, by its own members, one of the two being resident in New York:

1862. Henry Bauhael, New York.	Jared W. Daniels, F. Wadsworth, Dak.
1863. F. A. Castle, "	Alex. E. Jenner, Crestline, O.
1864. E. T. T. Marsh, "	L. A. Kastenbein, Louisville, Ky.
1865. C. A. Leale, "	W. D. Sweeney, Lexington, Ky.
1866. Le Roy M. Yale, "	J. P. Wallace, La Fayette, Ind.
1867. E. C. Harwood, "	J. T. Johnson, Washington, D. C.
1868. F. H. Bosworth, "	E. M. Kerr, Fulton, Mo.
1869. G. H. Sweeney, "	A. C. Graham, Dallas, Tex.
1870. Laurence Johnson, "	A. M. Owens, Evansville, Ind.
1871. V. P. Gibney, "	E. S. Emker, Brooklyn, N. Y.
1872. J. H. Burchard, "	D. W. Graham, Chicago, Ill.
1873. M. E. Tully, "	J. K. Kinney, San Francisco, Cal.
1874. F. S. Dennis, "	Rafael Young, Cuba.
1875. G. B. Hope, "	W. P. Glover, Georgia.
1876. L. H. Sayre, "	H. W. Rand, Nova Scotia.
1877. Geo. P. McCreary, "	

Professor Lewis A. Sayre offered a prize of two hundred dollars for the best essay submitted by an alumnus of the college upon the Etiology and Pathology of Pott's Disease of the Spine, the award to be made by the professors of pathology in the Bellevue Hospital Medical College, the College of Physicians and Surgeons, and the Medical Department of the University of the City of New York.

REMEDY FOR BURNS AND SCALDS.—Dr. G. F. Waters, of Boston, recommends the use of bicarbonate of soda as a local application to burns and scalds. The soda must be sprinkled over the injured part, and a wet cloth applied over it. Under this treatment the pain is almost immediately relieved, and the healing process goes on very rapidly.

SCHOOL OF PHARMACY IN PARIS.—A large school of pharmacy is to be opened in Paris in 1880, capable of accommodating six hundred working students.

BELLEVUE HOSPITAL.—Dr. Leroy M. Yale has been appointed visiting surgeon to this institution, vice Prof. A. B. Crosby, deceased.

## THE TRIGEMINAL NEURALGIAS.

A CLINICAL LECTURE DELIVERED AT THE UNIVERSITY HOSPITAL.

By H. C. WOOD, JR., M.D..

CLINICAL PROFESSOR OF NERVOUS DISEASES IN THE UNIVERSITY OF PENNSYLVANIA.

(Reported by SAMUEL M. MILLER, M.D.)

We give the name neuralgia to pain of an excruciating nature, extending along the course of a nerve. This pain is paroxysmal in character, and returns with renewed violence after a longer or shorter period of temporary remission. Neuralgia, like diarrhoea and dropsy, is a symptom of a general or special disorder, rather than a disease proper.

The causes of this condition are various. Among them may be mentioned local disease of the neurilemma, such as hyperemia and oedema, irregular menstruation, impaired general health, extremes of heat or cold, or pressure of a clot or tumor upon the nerve-trunk.

Neuralgia also frequently occurs during the progress of recovery from arsenical poisoning. The nervous system is generally in a state of profound depression, or nutritive inactivity, in this condition.

For purposes of convenience, we may divide neuralgias into two great classes, each class composed of several varieties. In the first class are all those forms of neuralgia in which the paroxysms of pain come on regularly, but at distant intervals. These forms are mostly symptomatic of several varieties of cachexia.

*First.*—There is the malarial form. This can generally be distinguished by the great regularity of the intervals between the paroxysms. The pain, which is usually felt at the supra-orbital foramen on one side of the face, comes on at a certain time every day. The history of malarial taint will aid in the diagnosis. The test treatment by large doses of quinia, thirty grains at a time, will determine conclusively the malarial origin.

*Secondly.*—We meet frequently with cases of megrim or migraine, the so-called hemierama. This morbid condition is generally either connected with disturbed menstruation, or is hereditary in its nature. Where the menstruation is at fault the pain is commonly gastric. Hereditary megrim usually attacks the first branch of the fifth pair of nerves. The pain, which centres in the eye or brow, the supra-orbital or temporal fossa, is very acute. There is nearly always nausea or vomiting, which passes off in the course of a few hours. This form of neuralgia, commonly known as "nervous headache," can be easily recognized by the long intervals between the attacks, the location of the pain, the history of menstrual disorder or hereditary disease, and the occurrence of sick stomach after the pain comes on.

The *third* variety is the anemic, chlorotic, or syphilitic, and is due to an impoverished, diseased state of the blood, anæmia, syphilis, or chlorosis. Sometimes the pain is localized in one of the branches of the trigeminus, sometimes in other nerve-trunks. The cause of this neuralgia is quite frequently, perhaps, over-exertion. The attacks are long and persistent.

*Fourth.*—Rheumatic neuritis, or faceache, is to be distinguished from periostitis by the locality of the pain. In some cases exploration will show that the periostitis is limited to some one tooth, which feels

longer than the others, and has in fact been pushed bodily upwards above the level of its fellows by the inflammation at its roots. By tapping all the teeth in succession with a key, or the blade of your knife, you will finally strike a tender tooth. Local swelling, too, will usually be noticed in periostitis. The existence of rheumatic pains in other parts of the body will usually strengthen the diagnosis. There will in most cases be a well-authenticated history of exposure.

The *fifth* variety is due to toxic causes, such as lead or arsenic poisoning. The blue line on the gums or the characteristic signs of arsenical poison will easily separate this variety from the others.

Under the second group of neuralgias, those coming on in sharp paroxysms at short intervals, and generally as reflex inductions of peripheral irritation or centric pressure, we find three separate forms: tic-douloureux, anesthesia dolorosa, and tic. These three forms usually go by the name of trigeminal neuralgia. The trigeminal is a nerve of both sensation and motion. By a smaller root, the gustatory, it also becomes a nerve of special sense. Therefore, either the sensation or motion, or both the sensation and motion of one side of the face may be affected through the branches of a right or left trigeminal nerve. The branches of this nerve are most exposed to neuralgic influences by reason of their passage through narrow canals or openings in bones, where they are readily compressed; and from the distribution of the nerve over a large cutaneous surface, more exposed to cold and changes of weather than any other part of the body. In trigeminal neuralgias the three special points of pain are the supra-orbital foramen, the infra-orbital foramen, and the mental foramen. These three are in one straight line in the face. If the neuralgia be limited to the first branch of the fifth pair, the pain spreads over the brow, eyebrows, and eyelids, and sometimes the eyes are attacked.

In tic-douloureux there is *both pain and spasm*. The causes of this form of facial neuralgia are usually peripheral in their origin, a decayed tooth, the pressure of a cicatrix upon one of the superficial nerve-branches, or local inflammation of the neurilemma. In some cases, however, the lesion may be centric, the pressure of a neighboring clot or tumor upon the nerve-trunk. In this form (tic-douloureux) the paroxysms are repeated at very short intervals; in some cases as many as five or six in the course of fifteen minutes, or even still more frequently. The sufferer will jump up and run round the room in his momentary agony. The late Dr. Pemberton, of England, is said to have stamped the bottom out of his carriage during one of these paroxysms of pain. Another doctor was caught making deep incisions in his face and applying the actual cautery. Frequent have been the attempts at suicide by sufferers from this dreadful agony; an agony which finally kills by wearing out the strength. The effect is generally limited to the nerve itself. In severer cases the mouth is drawn to one side, so that the saliva flows over the chin and neck. This saliva is altered in quality. In other cases the teeth chatter, the conjunctiva is injected, the tears flow freely, and a constant discharge from the nose is maintained. In very severe cases the course of the afflicted nerve is marked by a red line. The spasm may occur as often as once in every few seconds.

I bring before you, to day, a typical case of tic-douloureux, whose history I will give you.

CASE I.—I. B., aged fifty. Six months ago he first noticed a jerking and twitching, beginning at the

left mastoid process, and gradually involving all the muscles of the left side of the face and neck. At first, and throughout the continuance of the spasm, there was pain felt in the left auriculo-maxillary fossa. The pain and spasm were both violent for the space of one minute, the pain grew less, and entirely ceased at the end of another minute; in the course of several following minutes the twitching had also disappeared. When the attack first came on he had paroxysms at intervals of several days, but within the past month there have been very many paroxysms in very close succession—a dozen or more every hour. The patient, according to his own allowing, has been a moderate drinker. About twenty years ago he had an attack of gonorrhœa, which he thinks was entirely (?) cured. A year and a half ago he had an attack of rheumatism. He has had frequent touches of this since. There is no cardiac trouble; no sore points on pressure over any part of the body, and no spinal tenderness. Deep and hard pressure in the auriculo-maxillary fossa fails to cause pain. Once in a while the patient has only spasm without pain, and *vice versa*. His teeth are very imperfect. He states that the twitching and pain in his face cause at times an unusually large secretion of saliva, which is very tenacious, and exceedingly hard to expel from the mouth.

The above history illustrates nearly all the symptoms of tic-douloureux to which I have called your attention. It remains for us to determine whether this case of trigeminal neuralgia be centric or peripheral in its origin. The patient has been most carefully examined for a peripheral cause of the trouble, a local disease point, but without any result. I want to lay stress upon the absolute necessity of a most painstaking and minute examination of the surface of the face and of the mouth in cases of this kind, before giving a decision in favor of centric pressure. I remember the case of a woman who was brought to this city for treatment. She suffered the most excruciating paroxysmal pains about her jaws and round her head—it seemed at times as if her head were being bodily crushed in. The most minute examinations were made by various surgeons of this city for some obscure local point of disease, but without success. At last a minute orifice was discovered near a tooth. An incision was made, disclosing an opening into the antrum highmorianum. This incision was enlarged with the discovery that two nerves usually smaller than the finest hair had become swollen to the size of large bristles. Section of the two trunks was made above the point of swelling, and the pain disappeared at once to return no more.

No local disease spot can be found in the present case. This fact, joined with the observation that the spasm usually comes on before the pain, point quite conclusively to some centric point of pressure. The patient is an old man, and very probably there has been atheroma of the coats of his arteries leading to aneurism or rupture, and the formation of a clot near the origin of the left trigeminal nerve.

As regards the treatment of tic-douloureux—of course any peripheral cause of irritation may and should at once be relieved or removed. On the other hand, where the lesion or pressure is centric, the prognosis is far less favorable. Trousseau considers these cases epileptiform in character, and incurable. The treatment, which has been tried, has been that by a weak, interrupted current with the positive pole to the cervical spine and the negative pole to the auriculo-maxillary fossa, and *vice versa*. The patient says that he slept more easily after this treatment, but that it did not relieve the pain. Belladonna ointment and

the application of the actual cautery upon two occasions have both failed. The patient has been put upon a routine treatment of iodide of potassium and the bichloride of mercury, with the possibility of a syphilitic origin of the disease. Everything has signally failed to do him any good. Our only resource is opium, which must be given in doses continuous and large enough to dull the agonizing pain.

So much for tic-douloureux. *Anæsthesia dolorosa* is a form of trigeminal neuralgia where there is pain, but no spasm. This form is usually caused by a central tumor or clot pressing upon the sensory fibres of the nerve near its origin, and producing at one and the same time pain at the nerve-centre or brain, and anæsthesia or loss of feeling at the periphery. Hence the name *anæsthesia dolorosa*. Accompanying these conditions is generally found a palsy of one or both of the limbs on the side of the body opposite to the anæsthesia; that is, the clot, or tumor, or aneurism being on the right side of the body at the base of the brain, the anæsthesia would be felt and the pain referred to the same side of the face, and there would be palsy of the left arm or leg, or both left arm and leg. All sensations of pain are generally referred to the periphery; this explains the peripheral sensation of pain in *anæsthesia dolorosa*.

Some time ago a very interesting case of anæsthesia came to this hospital for treatment. A history was taken of the man at that time, which I will now read to you.

CASE II.—G. B. C., aged sixty-two; married; of temperate habits. About two years ago, immediately upon rising one morning, he had a severe attack of vertigo, attended with partial loss of power in the left leg. There was, however, no loss of consciousness. Under the use of a mustard foot-bath, etc., he got so much better that he was able to walk without much difficulty. At two p.m. on the same day he was cognizant of a very strange feeling in his left leg, and in a few minutes suddenly lost all power in that limb. The left hand was also slightly affected. With the loss of power of motion there was also a loss of sensation in the left leg, so that it could be immersed in boiling hot water without giving rise to any pain. The next day the patient had a very severe headache, with throbbing and a sense of bursting. Free venesection gave relief to this at once. During the next few weeks he regained power in his leg, and could walk quite comfortably with the assistance of a cane. At present there is distinct, but not perfect anæsthesia upon the upper surface of the foot and also upon the leg. Shortly after being bled, as above mentioned, he began to suffer from pain in the right side of the head. This pain has continued ever since with more or less severity. It interferes greatly with sleep at night. The pain is of a burning character. There are pain-points in the eyeball and in front of the ear. The pain does not change with changes in the weather. The man's general health is good. He feels sometimes as if there were a twitching of the muscles of the face, but there is no external, apparent spasm of these parts. The heart's action is slightly irregular, one beat in every twenty being dropped.

This case was evidently the result of a clot, which had been thrown out in a former attack of apoplexy, pressing on the roots of the right trigeminal nerve, just below the pons. This clot pressed on the sensory fibres of the nerve after decussation in the floor of the fourth ventricle, causing anæsthesia and pain referable to the right side of the face, but loss of power and sensation in the left arm and leg, since

the motor fibres of the cord upon which it presses decussate below the point of pressure.

The treatment of Case II. was by the continuous current. This was applied for from twenty-five to forty-five minutes at a sitting, and three times a week. This electrical treatment was temporarily successful only. The application of a blister to the ear also relieved for a short time, but afforded no permanent cure. A fluid drachm of a mixture containing half a drachm of croton chloral and six drachms of syrup was then ordered to be taken every night at bedtime. Phosphorus was prescribed in continuous doses, but still there was no permanent respite from the pain. The electric brush was applied frequently to the left leg, and twenty drops of chloroform were injected into the right side of the face. Still nothing but ephemeral relief could be had. The patient has returned several times to the dispensary, but no real improvement has yet shown itself in the case. You see how utterly powerless we are, with all our present knowledge put into practice, in hindering the regular course of this dreadful and obscure affection.

I have called your attention to the states known as *tic-douloureux* and *anæsthesia dolorosa*, and endeavored to illustrate for you by cases these two forms of trigeminal neuralgia. There yet remains a third to be mentioned. Simple tic, where there is *spasm* but *no pain*, is an exceedingly rare affection. No decided case of tic has lately come before our notice. The causes which may produce this abnormal condition are in general the same as those of *anæsthesia dolorosa*.

## Original Communications.

### THE ETIOLOGY OF DYSMENORRHEA CONSIDERED IN RELATION TO A NEW MECHANICAL PLAN OF TREATMENT.

By G. E. SUSSDORF, M.D.,

NEW YORK.

A REVIEW of the opinions entertained, in the past and present, respecting the etiology of dysmenorrhœa, though interesting, and important to a certain extent, in its bearing upon this subject, comprehends too great a field to be introduced in this paper, which is only intended to be a preliminary description of a new mechanical plan of treatment, which I have been recently practising with encouraging success, and which, so far as I am aware, has never before been attempted.

The cases treated are as yet comparatively few; consequently there are some phases of the disease in which it has not been tried; but in those which have been treated the results are sufficiently satisfactory to justify at least a description of the treatment, even at the present stage of my experience, reserving for another occasion the narration of cases, and a full consideration of the subject.

It is necessary to a proper comprehension of the operation of the means used, that an outline be given of the grounds I take respecting the etiology of dysmenorrhœa, as a basis for the treatment here proposed.

This general statement I believe none will dispute: That in a large majority, if not in all cases of dysmenorrhœa, there is more or less impediment to the flow in some parts of the canal of the cervix uteri.

The following statements I consider true also: That only in a small number of cases is the obstruc-

tion, or stenosis associated with or the result of a pathological state of the mucus and interstitial tissues of the cervix.

That in most cases the obstruction or stenosis is apparently unconnected with inflammatory or other *valent* pathological conditions of the tissues of the uterus or its cervix.

For the sake of convenience I shall divide the etiology of dysmenorrhœa into two classes, in accordance with the statements above made.

Those in which organic disease of the uterus or its appendages can be recognized by physical examination during the interval between the menstrual periods, and those in which no appreciable pathological conditions can be detected in these organs during the menstrual interval.

In the first class the following local pathological states may be enumerated as causes: Ovaritis, pelvic cellulitis, pelvic peritonitis, peri-uterine cellulitis, fibrous tumors, subinvolution, areola-hyperplasia, endometritis, polypi, fibroids in the cervix, inflammations of the cervix, and perhaps also displacements.

In the second, the following general pathological conditions of the system act as causes: Anæmia, chlorosis, plethora, rheumatism, gout, malaria, the cachexias, and syphilis, habits which debilitate the muscular and nervous systems, dyspepsia, a neuralgic diathesis, emotional temperament, mental disturbances, and, locally, congenital lack of development and malformations.

To this last class of cases, in which no recognizable disease of structure can be found in the tissues of the uterus or its cervix, I desire to call attention, and to state what I regard as the immediate or exciting cause of the dysmenorrhœa.

This I believe to be an active neurosis of the uterine system of nerves, inducing spasmodic action in the muscular fibres of the uterus, and especially in the *circular fibres of the cervix*.

This theory is not new; it has long been held by many gynecologists. Among those who earliest advocated this view was Dr. Bennet, who previously demonstrated the existence of a sphincter at the internal os. At this time a large number of the profession generally have adopted these views also.

There are many reasons for believing that the cervical muscular fibres contract spasmodically under certain conditions. This is in a measure proved by analogy. It is a well-known fact, as has often been cited, that the circular fibres of the outlets of other organs contract spasmodically and produce temporary stricture, as, for example, the œsophagus, the urethra, the rectum, the bronchi in asthma, and trachea in non-inflammatory croup. But I propose to go a step further in respect to dysmenorrhœa.

The active neurosis of the uterine nerves excites temporary spasm, but it does more—it establishes a morbid, vicious habit of contraction, which remains, in most all cases, after the disease which caused it has been removed. This is in many cases true of those of local pathological origin, as well as those resulting from systemic causes.

As normal menstruation becomes established, as a consequence of the physiological development of the organs of generation, and continues as a habit after these organs are matured, so also may the healthy performance of the function of menstruation become deranged, and a vicious habit result, as a consequence of interrupted development or impaired nutrition of these organs.

From considerable study of dysmenorrhœa, I have come to adopt these views respecting its etiology, and

to regard organic stricture or stenosis of the cervical canal as much less common than we have been taught to believe.

In the local treatment of dysmenorrhœa, the plan as generally pursued is to enlarge the narrow canal. To remedy the construction is to cure in a great measure the disease. Common experience teaches this. To effect this is by no means an easy matter. The instruments generally used to open the canal give no satisfactory results—indeed, they frequently fail altogether—and soon, from disappointment in their use, they are severally abandoned.

I refer to sponge and sea-tangle tents, to bougies, and expanding metallic instruments, of which there are a great variety.

From the time that dilatation was first practised, sponge and sea-tangle have been in use. Some find them answer a good purpose, while others have discarded them as dangerous. As regards sponge-tents, this prejudice I believe is well founded, and the various other instruments, though ingenious, cannot accomplish permanent benefit, because they cannot be used conveniently at the proper time, as will appear further on. In many instances, those who have been disappointed in the plan of treatment by dilatation, as usually pursued, have adopted the plan by incision and division, and have extended its application to all cases of narrowing. Notably among those in this country who claim that the knife is more effectual and less dangerous, is Dr. Marion Sims, whose opinions are certainly entitled to great respect. I do not wish, however, to touch upon this point, or to enter into a consideration of the relative merits of incision and dilatation, except to say that, according to my observation, the cutting operation should generally be limited to cases of organic stricture, cicatrices, tortions of the canal, and to some cases of flexion.

In most all other cases the dysmenorrhœa is not dependent upon disease of stricture, but is a consequence of a morbid, spasmodic habit of function.

The knife can accomplish no change in the perverted function, unless the integrity of the circular cervical fibres is destroyed; there must be a solution of continuity. To effect that, is to mutilate the organ. Even then the opening contracts again in many cases, and the dysmenorrhœa returns as bad as ever.

Why dilatation has failed in many cases to give good and lasting results, is a question not easily answered, still I think two factors have had much to do with it, viz.: unsuitable instruments for effecting dilatation, and an incorrect application of the means to the end. I have already intimated my objections to the instruments generally used. It is not necessary to repeat them here. I refer especially to sponge and sea-tangle. In the number of this journal for July 14, 1877, I described a new material for dilating purposes, tupelo (*Nyssa aquatica*), which I think admirably calculated for that purpose. It is safe and reliable, and much more rapid in its action than sea-tangle, and has never in my hands excited pelvic peritonitis or cellulitis. This is important. The incorrect application of the means to the end is the secret of its failure in most cases.

The cervix is very elastic and capable of great distention; it will return to its original condition very soon after the distending force is removed. Dilatation, therefore, by the ordinary means, does little more than temporarily stretch these tissues; it is seldom that it remains so longer than a few days. The idea that enlargement of the canal alone effects a cure is an error. It is not necessary to normal menstruation that the calibre of the canal should be large, since we know

there are many persons with a small canal who do not suffer from dysmenorrhœa, and others with a large one who do, and furthermore, a comparatively small opening is sufficient to carry off the menses, even in large amount, provided there is no obstruction to a continuous flow.

Actual enlargement is only necessary when the canal is narrowed by organized adventitious tissue.

The end to be attained in treatment is not enlargement of the channel *per se*.

The object should be to arrest and correct the spasmodic action, the morbid habit of contraction in the uterine and cervical muscular tissue.

Will dilatation accomplish this object? From present experience with the instrument represented here, I believe it will to a great extent, if applied in the manner I propose.

An important point in this plan of treatment is the time at which the dilatation should be effected. By the ordinary tents this can only be effected during the interval between the menstrual flow; by the instrument I use, it can be done just before and during the flow itself. The time at which the morbid habit of contraction shows itself is the time measures should be taken for its correction. The rule should always be observed; it is essential to success; it is the basis upon which rests the application of the principles called into action by this instrument.

The principles combined in this instrument are *expanding force* and *drainage*.

The expanding force of the tupelo insures dilatation of the canal and a consequent stretching of the cervical tissue. This is necessary, because there must be expanding force in operation at the time the morbid tendency to contract—the spasmodic action—comes on. An antagonistic power is thus brought to bear which arrests the spasm, and gives a normal direction to the action of the circular fibres of the cervix, which is that of *relaxation at the time of the flow*. This effect of dilatation is obtained to a limited extent by solid tents, when applied during the interval, and has usually been designated an *alterative effect*—but this is soon lost, as already stated, and as experience proves. By this instrument a powerful alterative impression is produced, which is never entirely lost.

In the centre of the tupelo dilator a small tube is placed, funnel-shaped at each end. This tube admits of the passage of the menses; otherwise dilatation could not be made at the periods—this is self-evident. At the same time that it admits of the easy escape of the fluid, it relieves the uterus and its appendages of irritations usually excited by the retained menses, and this, too, in the very beginning of the periods. The congestion of the deep-seated uterine blood-vessels, as well as the engorgement of those of the internal surface, are thereby relieved, and equally depleted, no matter whether the menstrual molimen be the simple hemorrhage of Cullen, or an exfoliation of the mucous lining of the uterus, as the investigations of Dr. John Williams seem to show. Much more might be said on all these points, but I have already extended my paper too much. I will only add a few details respecting the time and manner of using this instrument

Having diagnosed the case *non-inflammatory* in nature, and having carefully learned the time the pain begins and the flow comes on, local treatment should be instituted from sixty to forty-eight hours in advance of the expected period.

A solid tupelo tent should first be used, that will easily pass into the cavity of the womb; it should not have an expanding power greater than three-eighths inch diameter. This tent should be allowed to remain for ten to twelve hours, and then removed. This preparatory treatment tests the susceptibility of the uterus to irritation, and opens the cervix sufficiently to admit the drainage-tent.

There are some cases so inflammable that the least interference, even the passage of the sound, will excite trouble.

After the removal of the solid tent the parts should be allowed to rest until, as near as can be calculated, a few hours before the pain or flow comes on, when the drainage-tent should be introduced, and allowed to remain *in situ* from twelve to twenty-four hours, and then taken away. Sometimes at first its presence causes pain, but this usually lasts but a short time; should it continue unusually severe, the instrument may be removed by the patient. When the cervix touches the floor of the vagina, a ring pessary should support the uterus, and lift it sufficiently, so that the exit of the flow from the vaginal end of the tube will not be interfered with, else coagulation at the internal end might occur, and the instrument be expelled by the contractions of the womb. The instrument is usually self-retaining if care be taken to keep the patient in the recumbent position. As just stated, pain may be complained of the first time the instrument is introduced. This may be prevented in a great measure by covering the surface of the instrument with a preparation of sulph. morphine, or ext. belladonnæ, as follows:

R. Morphia sulph., gr.  $\frac{1}{2}$  to ..... gr. ij.  
Puly. sapo alba Castili..... gr. ij.  
M.

R. Ext. belladonnæ gr. i. to ..... gr. ij.  
Puly. sapo alba Castili..... gr. ij.  
M.

Or dry morphia sulph. alone may be used.

This is quickly absorbed.

The length of the instrument should generally be about one and three-fourths inches, or just long enough to pass the internal os; it should not project much into the uterine cavity.

In ordinary and recent cases it will not be necessary to introduce this instrument more than twice, the second time usually at the next period following but one. In old and obstinate cases, however, it may become necessary to use it oftener.

It is always advisable to give such general constitutional treatment during the intervals as is calculated to correct the dyscræia, and during the periods anti-spasmodic and anodyne remedies to relieve prominent nervous symptoms. Electricity may be used with advantage in some cases during the interval.

In conclusion, this question may be asked: Is not the instrument likely to excite inflammation when left in the cervix during the flow? I think not. It has never done so in a single instance thus far. The danger from tents is greatest before the flow comes on, when the blood-vessels are engorged; not during the flow, for this relieves irritation and engorgement, and prevents inflammatory reaction.

Here I shall let the matter rest for the present, believing that further experience will add other evi-

dences of the correctness of the views here expressed respecting the etiology and mechanical treatment of dysmenorrhœa.

41 WEST TWENTY-THIRD STREET.

## REPORT OF A CASE OF SEVERE INJURY OF THE FACE—FRACTURE OF THE BONES OF THE NOSE AND DESTRUCTIVE INJURY OF THE EYE, WITH REMARKS.

By JOHN D. NEET, M.D.,

VERMILION, KY.

IN the MEDICAL RECORD for Sept. 1, 1877, No. 356, Dr. S. C. Bull reports some very interesting cases of "Fracture of the Bones of the Face." The following case recently in my care involves certain points of surgical interest similar to the cases alluded to, and has seemed to the writer to be of sufficient importance to merit the following report:

On June 12, 1877, I was summoned to W. B., a boy æt. 12 years, being informed that he had been kicked in the face by a horse. I reached him one hour after the accident, and found him free from concussion or other constitutional disturbance, with a severe compound comminuted fracture with depression of both nasal bones, a depressed fracture of the nasal process of the right superior maxillary bone, and fracture of the nasal spine of the frontal bone. The soft parts were so lacerated and contused that my first impression on looking at the patient was, that there was entire destruction of the nose. Complicating this extensive injury was a laceration through the entire thickness of the right upper lid, half an inch in length, and a rupture of the ball of the right eye, running horizontally, and extending from the centre of the cornea to within two lines of the outer canthus. Through this opening the lens was seen protruding.

On account of the displacement of the broken bones, great difficulty was experienced in passing an instrument through the left nostril to the pharynx, while on the right side this effort was entirely without success. After removing two or three small fragments of bone and thoroughly cleansing the parts—hemorrhage having been free—with the assistance of Dr. Willis (the regular attendant), Dr. Layton, and Mr. Stitt (medical student), we proceeded to adjust the broken fragments. Considerable time and patience were expended in the satisfactory adjustment of the pieces, and the soft parts were then brought together with fine silk suture, and a cold compress applied. This being done, the eye received our attention. The lens, which was already protruding, made an easy escape by slight pressure on the ball, and was not followed by prolapse of the iris, capsule of the lens, or escape of the vitreous humor. A few drops of a solution of atropine (gr. ij. to f.  $\bar{3}$ i.) and a wet compress were applied. Symptoms of irido-choroiditis supervened on the eleventh day, ending in destruction of the eye.

Repair in the nose, however, progressed quite satisfactorily, excepting a slight slough of the free border of the right ala of the nose, and a small fistulous opening half an inch below the inner canthus, on the line of the naso-maxillary suture. The patient was discharged July 23d, with an excellent stump for an artificial eye, movement being perfect in every direction, and repair was complete in the nose, with the exception of the fistulous opening previously mentioned.

On August 5th a small piece of necrosed bone, one-fifth of an inch long and one-seventh wide, was re-

moved through this fistulous opening, which has since healed, and at this writing (Sept. 22d) the patient is apparently perfectly well.

In connection with this case there are three points of special interest:

1. The period of time that intervened from the day of the injury to the date of the supervention of symptoms of irido-choroiditis, being *eleven days*.

Previous to the sudden accession of these symptoms, the patient did not complain of any special inconvenience referable to the eye; but, in view of the pronounced contusion which it and the neighboring structures necessarily suffered, we would have rationally expected an early advent of this serious condition. We believe, however, this patient would probably have escaped it, had not the granulations of the cornea become adherent to those of the lacerated lid, causing irritation, active congestion, and the rapid development of a suppurative panophthalmitis. That this was the exciting cause of the attack no one could gainsay; for when I saw him on the 23d of June with the regular attendant (this being my first visit since the 14th), this union was so firm as to require a cutting operation to liberate the parts. (From this date the patient was under my individual care.)

Whether the attack of irido-choroiditis was delayed in any way by the early application of the *atropine* I do not assert; but from its known physiological action, viz., to dilate the pupil, diminish congestion, intraocular tension, and its further action as an anodyne, we see the rational propriety for its use upon strictly prophylactic principles, and it may have so acted in this case. From the fact that there was no evidence of irido-choroiditis until the eleventh day, is proof conclusive that the period when the disposition of the eye to take on active inflammation was greatest had been bridged over, and that it was only by the continuance of some source of irritation that the processes of repair gave way to those of waste and disease at the end of the eleventh day.

2. The limited necrosis following such marked comminution of the *ossa nasi*.

Aside from the two or three diminutive fragments removed when the parts were dressed, there was a loss by *necrosis* of a single piece of the meagre dimensions already mentioned.

Speaking of the circumstances laid down by various writers which are apt to result from fractures of the *ossa nasi*, including necrosis, fistula lachrymalis, etc., Hamilton, in his "Treatise on Fractures and Dislocations," says: "And it is certain that such consequences have occasionally followed; but they must generally be regarded as accidents due to the state of the general system, and as having no connection with the fracture, except as this injury served to awaken certain vicious tendencies."

That this passage will meet with unqualified acceptance I doubt very much, unless it has reference to simple and single fractures; for many are the well-attested cases in which necrosis has followed comminution of the nasal bones, when there was no reasonable supposition of the existence of a constitutional taint or diathesis. Instead of assigning such an occurrence to the category of scorbutic, scrofulous, or syphilitic manifestations with positive assurance, it seems to me that we are licensed to say that the necrosis stands in a causative relation to a factor which has interfered with the nutrition and constructive metamorphosis of the part, and instituted certain localized conditions, which, although inappreciable to the unaided eye, are destined to produce destructive organic changes. In recognizing the supremacy of

local causes in the majority of these cases, we should not lose sight of the fact and ignore the influence and power of certain cachexiæ to produce like results, especially when called into action by an exciting cause of local origin. In a young and healthy subject, where the acme of the reparative type is represented, and where other favorable conditions for rapid repair of injuries in this locality are fulfilled, the extent of necrosis will depend primarily upon the degree and kind of injury, and secondarily upon the blood state pre-existing or induced by the local disease.

3. The absence of obstruction or obliteration of the nasal duct and dacryocystitis.

This is certainly the most noteworthy feature of the case; and when we recall the extent of the injury and depression of the bones, we could scarcely have expected to escape obliteration of the nasal canal; but its prevention seems to have been due to the fact that, in the effort to prevent it, and to give more prominence to the bridge of the nose than was natural to the subject (before the accident the bridge was very low), the broken nasal process of the superior maxillary bone was elevated above its normal plane and drawn towards the mesial line, with the effect of causing the space between this bone and the lachrymal bone to be increased, and consequently increasing the transverse diameter of the nasal duct. The necessary manipulation required here can, of course, only be made in cases of compound fracture; and since more or less deformity usually follows fracture of the bones of the nose, even at the risk of *producing* slight deformity, an effort should always be made to so elevate the broken fragments as that there shall be the least possible or no encroachment upon the nasal canal.

The established rule in surgery in reference to making compound of simple fractures does not apply here, for a compound fracture in this locality does not differ materially in result from a simple fracture, and certainly does not necessitate the consequences which are the dread of the surgeon in compound fracture of the long bones. In a case of simple depressed fracture of the nasal process of the superior maxillary bone obliterating the nasal canal, I would not hesitate to cut down upon and elevate it, rather than incur the long train of formidable symptoms that constitute the opprobrium in the management of these depressed fractures. Upon the principle, too, of the "least sacrifice of parts," this operation is warranted; for, contrariwise, after many operative procedures—both dilating and cutting—we have to resort finally to destruction of the lachrymal sac (as in Dr. Bull's cases), which, besides being sacrificial, entails much pain and prolonged suffering. I do not believe there can be any comparison made between the course usually pursued and that just referred to; and while my experience does not entitle me to speak authoritatively upon the subject, I think we are justified in practising an operation that promises to avert the consequences of an obstructed nasal duct and an inflamed lachrymal sac. We do not disdain to make a compound of a simple depressed fracture of the skull when there is abrogation of function; then why should we not do the same when there is abrogation of function consequent upon a depressed fracture of the nasal process of the superior maxillary bone?

"If, in consequence of a blow received upon the *ossa nasi*, the nasal process of the superior maxilla be broken down, they may be lifted and adjusted in the same manner as the *ossa nasi*." (Hamilton.) In many such cases the fragments are so deeply depressed and impacted, that the elevating force brought to bear upon them from the nares is insufficient to properly

adjust them, and the operation of cutting down upon and elevating the broken bone is imperative if we would escape the consequences that would otherwise follow. The deformity in the above reported case is inconsiderable; in fact, the patient thinks he has a more "becoming" nose than before the accident, and there is no obstruction in the nasal or lachrymal passages.

#### NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

##### ADHESION OF SEROUS MEMBRANES—ILLUSTRATIVE CASE.

A MALE patient, æt. forty-eight years, had a severe attack of typhoid fever about twenty-five years ago. Previous to that sickness he was a healthy man, and subsequent to that date had had very good health, with the exception of occasional attacks of insomnia. This insomnia had led to headache and total inability to engage in any mental exercise until he had given his brain a certain amount of as nearly absolute rest as possible. His habits were correct. Since the attack of typhoid fever, however, he had not been able to sleep as well as before, nor had he been able to endure much excitement.

The question was asked, why should there be left upon the brain such a trace of the typhoid fever? The answer was, that it was doubtless due to extensive adhesions between the calvarium and the brain with its membranes.

Such a condition was believed to be of not infrequent occurrence in connection with typhoid fever, and that the persistent irritation and congestion of the cerebral convolutions, in consequence of such adhesions, sometimes led to epilepsy and frequently to insanity. The same condition was present as when a pachymeningitis followed fracture of the skull; the patient was liable to suffer from cerebral trouble at some future date.

##### QUESTIONS RELATING TO BRONCHITIS, PLEURISY, AND PHTHISIS—IMPORTANT CLINICAL FACT.

The case before us was one of ordinary chronic bronchitis, but certain questions were asked and answers given which were regarded as somewhat interesting.

In the first place, does bronchitis produce pleurisy? There is no causative connection between the two diseases.

Does phthisis give rise to pleurisy? Almost invariably, either at the very beginning or after the phthisis had advanced somewhat. Some have claimed that the first step in the development of phthisis is pleurisy. The truthfulness of this statement was doubted by the visiting physician, but it was believed that pleurisy is an element in phthisis in a large proportion of cases, and from the very commencement.

Why are pleurisy and phthisis so frequently associated? Because phthisis most commonly involves that part of the lung, the apex, which comes nearest to the pleura, and the inflammation is readily propagated from the former to the latter.

Inflammation affecting the parenchyma of the lung does not give rise to pain; pain is a prominent symptom of pleurisy.

Why does pleurisy give rise to pain? It is not be-

cause the pleura is more sensitive than lung-tissue, but by the movements of respiration traction is made upon the surface affected, perhaps adhered by inflammation, and pain is thus produced. The movements of respiration do not produce pain when the pleural surfaces are in a healthy condition; but when they become inflamed and adherent to each other, pain of a sharp, stabbing, intermittent character is produced, and depends directly upon a local cause. The consumptive patient, who has pleurisy, will point with the *finger* to the painful locality; whereas the pain attending bronchitis is rather a sense of diffused soreness, analogous to the diffuse soreness through the bowels accompanying diarrhoea, and its location is referred to by using the *entire hand*.

Does bronchitis occasion ulceration? Only in very exceptional cases. Therefore, although an immense quantity of pus may be secreted and expectorated, it is produced upon a mucous membrane the surface of which is unbroken.

What clinical difference between phthisis and bronchitis results from this fact? The expectoration of a pint of pus in bronchitis is not attended with as much systemic effect as the expectoration of a very small quantity in connection with phthisis; and the reason is the pus, although it may be decomposed, is not so readily absorbed, because of the intact condition of the mucous membrane in the bronchitic patient.

Hectic does not accompany simple bronchitis, notwithstanding the immense quantity of pus which is sometimes secreted. On the other hand, hectic will be developed in a case of phthisis where only a comparatively small amount of pus is secreted, if there is no barrier set up to prevent its absorption. Pyæmia is developed where there is no limiting membrane; hence, as soon as a simple bronchitis becomes a peri-bronchitis, all the results of phthisis may be developed.

Some pathologists maintain that phthisis commonly arises from bronchitis. They say that a person first has a catarrh which extends into the bronchial tubes, a peri-bronchitis follows, broncho-pneumonia is developed, and then phthisis.

Exception was taken to this view, because, if true, phthisis should be developed upon both sides at the same time, inasmuch as ordinary catarrhal bronchitis, as a rule, involves both lungs. If there is any fact in the history of phthisis which is more prominent than others, it is that only one lung is involved at the commencement of the disease; indeed, only a small portion of the lung is affected, and the limitation can usually be distinctly mapped out. It is an important clinical fact that frequency of respiration bears no such relation to bronchitis as it does to phthisis. A great amount of bronchitis may be present, and yet not be accompanied by any increased frequency of respiration. A greater length of time is required for the air to make its entrance and exit in bronchitis than in phthisis, because of the want of elasticity in the lung in expiration, and usually there is more or less obstruction to inspiration; the patient perhaps labors for breath.

Increased frequency of respiration was regarded as one of the earliest symptoms of phthisis—the disease, although limited in extent, giving rise to a more frequent respiration than is seen in a bronchitic patient, with lungs over which all kinds of auscultatory signs can be heard.

##### LOTION FOR CONTUSIONS—HOW TO GET RID OF A BLACKENED EYE.

If one is so unfortunate as to get hit on a peeper, it

is said that the effects can be removed within two or three days in the following manner: If there is much pain, foment the parts continuously with simple hot water until it ceases, and then keep the contusion constantly wet with the following lotion:

R. Muriate of ammonia . . . . . ℥ ij.  
 Vinegar,  
 Water . . . . . ℥̄ss ℥ ij.  
 M.

## Progress of Medical Science.

**EARLY SYPHILIS IN THE NEGRO.**—In a paper read before the Baltimore Clinical Society, Dr. Atkinson pointed out some interesting peculiarities of early syphilis occurring in the negro. The whole number of cases analyzed was one hundred, of which forty-five presented the primary lesion; during the same period of observation but twenty-four cases of chaneroid were observed. The chancres were marked by extensive ulceration, abundant secretion of pus, and considerable tenderness. The specific induration varied, was not unfrequently obscured by inflammatory infiltration, and in vulval chancres was commonly absent. The indurated inguinal glands were remarkable for their immense size, great tenderness, and liability to run on to suppuration. Suppuration of the cervical and submaxillary glands was observed in eight cases. Of the eruptions, the papular was the most frequent; at first the papule is of a darker, later of a lighter hue than the rest of the skin. Rheumatoid pains, synovitis, and iritis were observed much more frequently than is the case with whites. All these variations Dr. Atkinson traces to the influence of the scrofulous diathesis, which he declares to be present in the majority of negroes, especially where there is an admixture of white blood. The diathesis delays, but does not prevent recovery, and induces a marked predisposition towards the return of symptoms rendering necessary the exercise of constant vigilance.

**SUBCUTANEOUS SECTION OF THE HUMERUS.**—In the transactions of the College of Physicians of Philadelphia, Dr. Mears reports a case of old dislocation of the shoulder in which subcutaneous section of the humerus was practised with immediate and lasting benefit. The instruments used were the tenotome and saw devised by Mr. Adams for subcutaneous section of the femur. The knife was entered on the outer side of the arm, two inches below the acromion process, and the periosteum divided; the knife was then withdrawn, and the saw introduced. After division of the bone the arm was secured in the Velpeau position. The wound closed, without suppuration, in three days, and on the tenth day passive motion was begun. The pain ceased immediately after the operation, and did not return. An examination some months later showed the formation of a very useful joint, with marked improvement in the motions of the hand, and gradual return of the strength of the arm. Dr. Mears reviews hastily the dangers attending attempts of reduction of old or chronic luxations, and concludes his paper by recommending this operation as simpler, safer, and more successful.

**PERIOD OF MAXIMUM BIRTH-RATE.**—Prof. Landis, of Starling Medical College, has tabulated the hour of birth in three hundred consecutive cases of labor at full term, with the view of obtaining the period of maximum birth-rate. The result gave the maximum

rate from 5 to 8 A.M., and a second rise from 6 to 11 P.M. The minimum rate was from 8 to 9 A.M., and 11 to 12 P.M. The rate from 6 P.M. to 6 A.M. exceeded the rate for the remainder of the twenty-four hours by 13½ per cent. From this small number of cases the Professor hesitates to draw any positive conclusions, but suggests the possibility of solar and atmospheric influences having some power in determining the period of activity for the uterus; he considers it probably more influential in terminating intervals of inertia, than in exciting the primitive contraction.—*Phila. Med. Times*, Sept. 1, 1877.

**THE METASTASIS OF TUMORS.**—Unsuccessful attempts have often been made to inoculate animals with fresh pieces of sarcoma and carcinoma. In consequence of this want of success, Drs. Cohnheim and Maas determined to try the effect of inoculation with a physiological substance whose reproductive capacity after removal from its natural site is well known, namely, periosteum. Small pieces of periosteum were cut from the tibia and introduced into the venæ jugulares of hens, which were killed in from three to twenty-seven days. Up to the sixteenth day the piece of periosteum could be felt as a hard mass in the pulmonary parenchyma, but after the twentieth day external examination of the lung failed to reveal the site of the foreign body. This was found in the pulmonary artery, rolled up into a solid cylinder. In specimens examined from 3 to 5 days after the inoculation, the piece of periosteum was found simply thickened, more resistant, and permeated with migratory cells. In from 10 to 12 days, hyaline cartilage cells were found on the inner surface of the periosteum; on the 15th or 16th day, true bony lamellæ were always found. New vessels grew into the periosteal embolus from the vasa vasorum, exactly as they do in an ordinary embolus, but the arterial walls took no part in the changes, beyond the development of vessels. After the 20th day, the periosteal embolus was much shrunken, and no traces of ossification could any longer be discovered, and at the end of a month the embolus had entirely disappeared.

These experiments demonstrated both that isolated bits of tissue can grow and proliferate within the blood-vessels, and that the healthy organism is capable of separating and removing from the body such substances. From them the experimenters deduce the theory, that individuals who suffer from generalized tumors must be wanting in this capacity to remove superfluous substances. They claim that a tumor is not in itself malignant, but that it becomes so only when it affects an individual, whose resisting capacity is reduced below the normal point. The constituents of all possible sorts of tumors must certainly often find their way into the blood-vessels, and more especially into the lymphatics; but as long as the nutritive changes in the individual are carried on with the normal energy, this accident is perfectly harmless. When, however, the resisting power of the organism is diminished from any cause, the tumor can extend into neighboring tissues and form metastases. It is asserted that this hypothesis explains the generalization of so-called benign tumors, the sudden commencement of growth in tumors that have long remained sharply circumscribed (in the mamma), and finally the generalization of a tumor in a single tissue or system (carcinomatous metastases in various bones, complicating carcinoma of the breast). Finally, it is claimed that this hypothesis explains the want of success in the inoculation of healthy animals with carcinomatous masses.—*Centrabblatt für Chirurgie*, August 4th.

## THE INTERNATIONAL MEDICAL CONGRESS AT GENEVA.

THE organization of the fifth session of the International Congress of the Medical Sciences, held at Geneva, Switzerland, last month (September 9 to 15), as well as the range of topics discussed, presents some features to which it may be well to call the attention of medical societies in this country. This is especially true as concerns those features which are essential to the rapid transaction of routine business and to the utmost efficiency of the several sections in their special departments of scientific inquiry. A committee of organization, supported by five sub-committees, and sixteen by-laws of two or three sentences each, map out the business and order of the session; limit its duration to one week; prescribe a payment of twenty francs, in return for which each delegate receives a copy of the transactions of the congress, and put the members in possession of all the information required to take an intelligent interest in the proceedings. The division into sections, each section reporting to the assembly at large, was at once simple and comprehensive. First in order, of course, comes the section of medicine; then, that of surgery; thirdly, that of obstetrics and gynecology; fourthly, the section of public medicine, a department of investigation to the importance of which the medical societies of the United States have given brilliant testimony during the present year. The biological section, with its more general range of physiological researches, stands fifth on the list, and is followed by the very special section of ophthalmology, otology, and laryngoscopy. A carefully prepared programme of the session, seance by seance, put both members and the general audience *au courant* with the order of business for each day. The opening day was, as a matter of course, given up to gratulatory discourses delivered by officials; and then, from day to day, a series of important papers

were read and discussed in full congress, the several sections pursuing their work as independent organizations. A glance at the titles of some of these papers will best illustrate the scope and methods of European medicine. Prof. Broadbent, of London, submitted a paper on Cerebral Localizations; Prof. Lombard, of Geneva, on Malaria in Europe and North America; Prof. Schiff, of Geneva, on the Function of the Spleen; Prof. Hardy, of Paris, on Parasitic Affections of the Skin; Prof. Bonclard, of Paris, on the Causation of Typhoid Fever; Prof. Vogt, of Geneva, on the Entozoa of Man.

The same minuteness, with a view to facilitate intelligent discussion, was carried into the section programmes, each member being supplied with a sub-programme in pamphlet form, specifying the questions raised by the papers to be read, giving the main conclusions of the author, carefully classified, and appealing to the members for verifying facts in instances where the author had been unable to arrive at a definite conclusion. For instance, in default of facts demonstrating the direct contagion from man to man of typhoid fever, Prof. Bonclard asks for facts tending to establish the mediate noxiousness of the excretions and other waste matter from typhoid patients, and for facts relative to the air and water poisoning associated with that disease. In the same manner, Prof. Revilliod's leading conclusions as respects diphtheria are specified in the programme, and facts tending to establish disputed points are solicited. Or, again, in the section of public medicine, Prof. Magnan, of the Hôpital Sainte-Anne of Paris, states his salient conclusions on the Influence of Alcoholism upon Mental Diseases; or in the section of biology, Prof. Broadbent gives a summary of his researches as to the functions of the nervous centres of the brain, and submits certain unsettled points for information.

This reduction of the intellectual work of each section to a species of university routine not only facilitates discussion, but enables each member of the section to recall and classify facts, consult notes and memoranda of cases beforehand, and prepare well-digested rejoinders, instead of talking at random, as even venerable professors sometimes will when an issue is suddenly sprung upon them. While, however, this minute organization of the intellectual work of a learned society conduces to pointedness and rapidity of discussion, tacitly at least it abridges the liberty of suggestion that forms one of the valuable elements of meetings less rigid in their rules, and more supple to the unexpected turns and issues which necessarily occur in debates upon unsettled scientific questions—and of all the sciences, that of medicine is perhaps the most abundant in disputed points. Our own larger liberty of discussion and greater freedom from routine have, therefore, their special advantages, while the silent disapprobation of a body of his fellows generally suffices to suppress the babble of a random talker.

It certainly speaks well for the reputation of medical science in this country, that out of three delegates to the congress from the American Medical Association, two—Dr. J. Marion Sims and Dr. Edward Seignin—were placed upon the list of honorary presidents (*présidents d'honneur*), while Austria and Germany were accorded only one each.

A paragraph from the opening address of President Vogt, relative to recent progress in methods of medical investigation, is so applicable to the doings of our own medical societies this year that it will bear translation:

"By experimental methods of inquiry, the same rigorous precision has been introduced into physiological and pathological studies, that exists in the physical sciences. Guess-work has thus been banished as far as possible, and replaced by positive results, capable of being verified and controlled. The exactness of instrumental inquiry has been followed by more rigorous methods of reasoning; and if the probabilities of error have not been completely eliminated, they have been reduced to a minimum, and the limits of possible error indicated with precision."

#### RESPECTABLE PROFESSIONAL STANDING.

THERE are few, if any, who can afford to be entirely independent of the opinion of their associates. A medical man may declare his freedom by acting as an individual rather than a part of a great and influential community; but he does so often at the risk of losing his influence, not only as a medical man, but as a member of a learned profession. We confess that we intend these remarks to bear upon the necessity of belonging to medical organizations, or in some way identifying oneself with professional interests generally. Although this is a fact which is not so well appreciated in medical circles as it should be, we now and then have an illustration of its importance. Especially is this the case when a medical man appears as a witness. Here, in order to give his testimony its full force, he has to prove to the jury his capability to testify not only by his education and qualifications, but his affiliation with his profession. In a recent instance of this sort a medical gentleman of this city, who openly boasted that he did not care to become a member of any medical society, was severely handled by the attorney of the opposite side, who made it appear to the jury that the gentleman in question was not regular, and that his testimony should be taken with that allowance given to all suspicious witnesses. The result was what might have been anticipated. There is no argument even in a court of law against respectable connection and high standing in the profession, while a suspicion of the contrary is always a handle for an adversary. The moral of all of which is that it is safer to be respectable, even if it does incur the necessity of belonging to some recognized medical organization.

#### THE BOGUS DIPLOMA TRAFFIC.

AGAIN the unpleasant subject of bogus medical diplomas is brought up! The Mayor of Philadelphia has just received a letter from Lucius Fairchild, U. S. Consul at Liverpool, to the following effect, viz.: "Will you kindly inform me whether or not the Eclectic Medical College of Pennsylvania, named on the enclosed card, is duly authorized to grant diplomas to which faith and credit could be given? I ask this because I have been applied to to certify signatures, etc., on a diploma issued by that college. In view of the frauds which have been practised by the sale of worthless diplomas purporting to be issued in Philadelphia, I desire to exercise extreme caution in such matters." The enclosed card was "Eclectic Medical College of Pennsylvania, Sessions of 1871-72, order of lectures, etc., etc."

The Mayor at once began an investigation of the matter, which resulted in the following very interesting revelations:

Acts of Assembly relating to the College. February 25, 1850, an Act incorporating the Eclectic Medical College of Pennsylvania. February 26, 1853, the American College of Medicine in Pennsylvania was incorporated. (This was an omnibus bill, and was not published in the authorized Acts of Assembly until 1861.) May 7, 1855, a supplement to the former Act, of February 25, 1850, providing that the word "Eclectic" be stricken out, thus leaving the title the "Medical College of Pennsylvania." February 15, 1860, supplement to the Act of February 26, 1853, changing the title of the American College of Medicine in Pennsylvania, to the "American College of Medicine in Pennsylvania and the Eclectic Medical College of Philadelphia." May 21, 1865, a supplement to the Act of February 25, 1850, incorporating the Eclectic Medical College, and a supplement to the Act of February 26, 1853, incorporating the American College of Medicine, provides that the titles of the American College of Medicine in Pennsylvania and the Eclectic Medical College of Philadelphia, shall be changed to the "Philadelphia University of Medicine and Surgery." February 18, 1870, an additional supplement to the Act incorporating the American College of Medicine in Pennsylvania, etc., conferring additional powers of teaching *in all branches of the arts and sciences, and of conferring the usual degrees, and of establishing a hospital, and of issuing stock in sums of \$50 or upward, to purchase buildings essential to the establishment and successful working of said university and hospital.* (The italics are our own.) March 22, 1872, two Acts reciting that a committee of the Legislature has ascertained that the Philadelphia University, or American College of Medicine and the Eclectic Medical College of Pennsylvania have been engaged in the unlawful sale of medical diplomas to persons not qualified, etc., and repealing the two charters and supplements. (This was the time of the

first excitement in medical circles, caused by the discovery of the wholesale distribution of bogus medical diplomas by this institution, both in this country and abroad.) In the same year, 1872, an appeal was taken to the Supreme Court, and it was decided that the Legislature had no right to repeal a charter, but that the proper course to pursue was to apply for a writ of *quo warranto*, and set out therein the particular instances of grievance. This has not yet been done, and the College is, therefore, virtually still in existence.

The above is the truthful history of the great Philadelphia bogus medical college in epitome. What a shameful tale these official records of charters obtained and charters changed and charters combined, of supplements, and repeals, and appeals, tell! Here is twenty-seven years of such procedure laid bare! First, one institution selling bogus diplomas and getting into hot water for it; then the same men getting up another affair and carrying on the same illicit business there; then getting unpleasantly situated there; then combining the two affairs and trying the same game; then uncombining the two affairs and giving them new names; then combining the two uncombined affairs under a still newer title, and still by hook or crook managing to carry on the shameful business! Finally, public action in the repeal of the charter, and action of the courts making that repeal of none effect! And the place "*is, therefore, still in existence!*"

We do hope our neighbors will take some quick, sure step and blot out at once and forever the "Great Bogus Diploma Mill" that for so long a time has been trying to throw the burden of its shame upon the profession in Philadelphia.

## Reports of Societies.

### NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, October 18, 1877.*

DR. S. S. PURPLE, PRESIDENT, IN THE CHAIR.

#### THE OBSTETRIC FORCEPS—DEMONSTRATION OF A NEW PRINCIPLE—DESCRIPTION OF M. TARNIER'S NEW INSTRUMENT.

PROF. FORDYCE BARKER, before presenting Tarnier's new obstetric forceps and demonstrating the principle upon which the instrument operated, gave a brief outline of the progressive change which had taken place in obstetric teachings since the early part of the present century. As was well known, early teaching was to the effect that the forceps should not be used except under circumstances where it became conclusive that without the instrument delivery of the woman could not be effected.

Subsequent teachers favored its use much more frequently, but they were so laden with former prejudices against the use of the instrument, that they fell but little short of the teachings of their predecessors. The instrument was regarded as one of great danger,

and that opinion was instilled into the minds of pupils. By comparing statistics, judgment could be formed regarding the effects of these teachings.

Of the older teachers and writers, Ramsbotham used the forceps only in one out of 729 cases; Clark, in one out of 742; Collins, in one out of 617; Churchill, in one out of 546; Battie, in one out of 139.

Among the later writers and teachers, Naegele employed the instrument once in 31 cases; — once in 14 cases; Hamilton, of Scotland, once in 7 cases; Siebold, once in 7 cases; and George Johnson, once in 11½ cases, and, as he regarded, with a great saving to both mother and child.

There were three reasons why the celebrated men who operated in the early part of the century entertained such horror of the obstetric forceps.

1. They were entirely ignorant of the mechanism of labor.

2. While they greatly exaggerated the dangers both to mother and child from the use of the forceps, they did not recognize the danger which results to both mother and child from prolonged labor.

3. They confounded the difficulty and skill demanded in their use in the comparative few cases in which the instrument was required, when the head of the child was at or above the superior strait, with the very many cases in which we now use the instrument when the head is in the cavity or at the outlet of the pelvis.

The causes which had contributed to effect a change in opinion and practice had been, *first*, a knowledge of the mechanism of labor; *second*, a paper contributed by B—, of Dublin, in 1829. Previous to that date it had been stated that for forty years the forceps were almost never used in that country, owing to the great influence of the older teachings in obstetrics. Dr. B— produced his paper in which was the statement that he had employed the forceps in 105 cases without a single fatal result to the mother or a single death to the child that could be ascribed to the instrument.

Next came a paper from Sir James Y. Simpson, who demonstrated that both maternal and infantile mortality increased in a direct ratio with the increased duration of labor.

Subsequent to the publication of Dr. Simpson's paper, Dr. Barker read a paper before the Medical Society of the State of New York, on the use of the forceps, which was published in their volume of Transactions for the year. At the time, the paper was severely criticised, but Dr. Barker believed it would not receive the same criticism at the present day.

Reference was then made to various publications since the year 1860, but perhaps the most remarkable was the last report of Dr. George Johnson, of Dublin, master of the — Lying-in Asylum. It should be recollected that one of Dr. Johnson's predecessors employed the instrument only once in 742 cases; another only once in 617 cases; and one of those predecessors had said that he had never resorted to its use in private practice. They had, however, employed the perforator 141 and 149 times. Dr. Johnson reported that he resorted to the forceps once in 11½ cases, and that in all the cases of labor which had been in the institution he had used the perforator only three times.

Dr. Dunster, of Ann Arbor, had given, in a paper lately published, a most complete summary of the doctrines entertained at the present time regarding the use of the obstetric forceps.

Dr. Barker further remarked that the plain practical question to be settled in every case was, which

is safer for the mother and child, to use the forceps or permit further delay in the completion of labor?

The danger in the use of the forceps to both mother and child was to be considered with reference to two points: *First*, with reference to the danger when the head was in the cavity or at the outlet of the cavity; and *second*, the danger when the head was at or above the superior strait.

In the hands of an obstetrician who thoroughly understood the mechanism of labor, who had proper instruments, and who operated only in appropriate cases—those in which there was no disproportion between the fetal head and the diameters of the pelvis through which it must pass—there could be no danger in the use of the forceps. There could be danger only when there was such disproportion as required such compression of portions of the cranium of the child as to produce intercranial lesions, or injury to the mother by violent pressure upon the soft parts.

It was believed to be unnecessary to discuss that proposition. There was a word to be said, however, with reference to delivery of the head when in the cavity, or at the outlet of the pelvis, in order to prevent laceration of the perineum. The question might with propriety be asked, is not the forceps a dangerous instrument because of the tendency to produce laceration of the perineum? Dr. Barker's own answer to that question was, that the forceps, when properly used, was an instrument calculated to preserve rather than rupture the perineum. The result depended entirely upon the manner in which the instrument was used. If the vulva was found so narrow that the head could not pass without producing laceration, of course rupture of the perineum would occur, even though the head was allowed to pass through unaided by art. Again, the danger of laceration was very much increased by long continued pressure of the head of the child against the soft parts of the mother. Dr. Barker's own practice was, when the vulva became fully dilated, to remove the forceps, and then introduce the fingers into the rectum, pull the head forward and deliver. He never completed the delivery by rapid removal of the head through the outlet. Used in that manner, it was believed that the forceps preserved rather than destroyed the perineum. During an experience of twenty-five years Dr. Barker had never had laceration of the perineum, from the use of the forceps, occur to such an extent as to require subsequent surgical treatment.

*Secondly*, with reference to danger to mother and child from the use of the forceps when the fetal head was at or above the superior strait. The danger in that instance was from too violent pressure of the head of the child, or from making traction in the wrong direction, or from compression of the soft parts of the mother.

The question to be considered is, whether the safety of the mother and child was not greatly increased by early delivery rather than by following the teaching of the older writers who never used the long forceps, but always resorted to the perforator and craniotomy, thereby inevitably sacrificing the life of the child. There were three essential points to be considered with reference to delivery from the superior strait:

1. The operator should thoroughly comprehend the cause which made the operation necessary.
2. The mechanism for overcoming that cause should be thoroughly understood. The operator should know perfectly what the relation was between the diameters of the fetal head and the diameters of the pelvis through which it was to pass, in order that he

might know how and when to change the direction of the traction which should make the diameter of one correspond with the diameters of the other.

3. The operation should be performed slowly. One-half hour was the least time that should be occupied in bringing the head down from the superior strait.

Finally, in safe delivery from the superior strait very much depended upon the instrument employed. Dr. Barker ordinarily employed Simpson's forceps. He rarely used the short forceps. In cases in which there was required simply a slight increase of force, the short forceps were sometimes used to save the woman from two or three hours of suffering, and were applied without change of position, and often without suspicion on the part of the patient that the instrument was being employed.

Dr. Barker then made brief allusion to the history of the forceps, and came to the description of a new instrument devised by M. Tarnier of France. It was claimed by the inventor that his instrument accomplished three things:

1. It enabled the operator always to make traction in the direction of the axis of the different straits.

2. It allowed the fetal head such mobility that it might take the direction it would normally take in passing through the pelvic cavity without the use of any instrument.

3. It furnished a guide which showed the operator in what direction traction should be made to correspond to the axis of the pelvis.

Dr. Barker then described the instrument and demonstrated, by means of diagrams, the principle upon which it was constructed. The theory was briefly as follows: When the head of the child was at or above the superior strait, it was impossible to make traction with the forceps in ordinary use, in the exact axis of that strait, because of the resistance offered by the perineum. It was necessary to make traction in a line somewhat forward of the exact axis of the strait, hence a certain amount of force was wasted against the posterior surface of the symphysis pubis. In Tarnier's instrument this was obviated by a curve in the handle which permitted traction to be made in the axis of the superior strait without making undue pressure backwards on the soft parts.

Traction was made by means of independent rods which were attached to the posterior border of the blades of the instrument and terminated in a cross-bar just beyond the handles. The instrument was adjusted in the ordinary manner; the blades locked and fastened, and the handle contained a mechanical arrangement for regulating the amount of compression brought to bear upon the head of the child. To this part of the forceps Dr. Barker objected, because he believed that the degree of compression should always be under the immediate control of an intelligent hand.

Now, when the instrument was applied to the fetal head at the superior strait, traction was first made backwards and downwards, but as the head approached the cavity of the pelvis the handle of the forceps began to rise, thus indicating in what direction traction should be made to correspond to the axis of the pelvis through which the fetal head was passing. As the handles arose the tractor was brought up to it, and so we had an automatic indicator which gave *direction* to the force of the operator. The instrument was strong, and that was regarded as an argument in its favor, for it was claimed as an axiom that, in the obstetric forceps, *power was safety and feebleness was danger*.

PROF. JAMES P. WHITE, of Buffalo, was introduced

to the Academy, and remarked that he had been led to believe the reason why the forceps was used so much more frequently on the Continent than in the British Dominions, was because the operators on the Continent used the long, double-curved instrument. In the countries where the short forceps only were employed the perforator was very commonly resorted to. It was doubtless true that where the forceps were most used, the perforator was least employed. Dr. White believed that the forceps should be used much more frequently than it is; that it should be used skilfully, but only by those who were thoroughly familiar with the mechanism of labor and had sufficient mechanical knowledge to handle it properly. The doctor then gave a detailed description of his own instrument, sometimes called Du Bois' forceps. He was unable to see the utility of Tarnier's instrument, and believed it to be a substitute of mechanical device for skill. It was claimed that the perineum could be pushed back sufficiently far to allow traction to be made in the axis of the superior strait by means of instruments now employed, and that a finger, guided by intelligence, was a sufficient indicator as to the direction in which traction should be made. If a thorough knowledge of the mechanism of labor taught the operator in what direction his traction should be made, why be troubled with a mechanical indicator? The doctor believed that in twenty years from now Tarnier's instrument would be found among obstetric curiosities. He also believed that it was unskilful to rupture the perineum while delivering a woman with forceps.

PROF. W. T. Lusk was not prepared to accept Tarnier's instrument as being any more desirable or even as desirable as many forceps now in common use. The objection to the old instruments because the operator was not able to make traction in the exact axis of the superior strait he did not believe was warranted, for there was no danger of inflicting injury upon the perineum by depressing the handles of the forceps so as to make traction in the proper direction. When the head had been brought into the cavity of the pelvis, it could be easily delivered with the ordinary forceps, and it was to be noted that in so doing, as the traction intermitted the handles would rise, and consequently there was no need whatever of an extra indicator.

Again, he regarded the new instrument as objectionable when used at the superior strait, because in such cases there was very commonly contraction of the pelvis in its antero-posterior diameter. The consequence was, that the head of the child did not engage in the oblique diameter nearly so often as in a somewhat transverse diameter. The result was, that when the forceps were applied one blade rested over the occiput and the other over the frontal region, and although the tissues against the pubis might be saved from pressure by the instrument of Tarnier, the operator did run the risk by its use of injuring the tissues between the head of the child and the promontory of the sacrum. He favored the use of the straight forceps used by Prof. Taylor when the head was at the superior strait of the pelvis; and after it had been brought into the cavity the main difficulty was overcome, because the double-curved forceps could be used with comparative ease.

PROF. ISAAC E. TAYLOR remarked that the straight forceps he used was Pitkin's instrument. He believed that by the new instrument we set aside what nature had taught us, and was unable to see any advantage whatever that could be derived from its use.

The Academy then adjourned.

## Correspondence.

### ELECTRICITY IN THE TREATMENT OF DYSMENORRHOEA.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In the RECORD of October 6th the theory is enunciated that, in dysmenorrhœa, "an irritation originating in the uterus is propagated through its sensitive nerves (the sacral nerves) to the nervous centre, whence it is transmitted to motor nerves (plexus uterinus) which produce the spasmodic contraction of the uterus," and that a cure for this condition is effected by directing a galvanic current of "considerable" intensity towards the genito-spinal centre, and a current of "moderate" intensity towards the medulla oblongata. That electricity is of more or less value in the various forms of menstrual disorder is now sufficiently established, but that it can be relied upon with any degree of certainty, either in establishing the menstrual function, or in relieving the excessive pain with which it is so frequently associated, is far from evident.

The theory above stated may or may not be tenable; it is as yet a mere matter of opinion. But my object in writing is simply to suggest that whether true or not it is impossible, with our present knowledge, either to obtain uniform results in the electrical treatment of dysmenorrhœa, or to confidently assert that the indications are always for a special current or method. In an article, entitled "General Electrization, and its Use in Certain Uterine Affections," read before the New York County Medical Society, and subsequently published in a number (September 15, 1866) of this journal, I detailed a number of cases of dysmenorrhœa, aggravated in their symptoms and persistent in their course, that were completely and permanently relieved. The condition with which the dysmenorrhœa was associated in these cases was mostly one of anæmia and exhaustion, and the treatment was based on the now well-attested tonic properties of general faradization.

Galvanization of the spine along its whole course, as well as over the genito-spinal centre, has in my own, as well as in the experience of others, proved at times entirely successful, although I confess that it has never occurred to me that the "*medulla oblongata*" demanded special attention in the treatment, by the use of a "moderate" current. It would be easy to detail from my clinical record quite a number of cases that have been relieved by the application of electricity, but, on the other hand, an impartial statement would necessitate the enumeration of not a few failures.

I offer, therefore, the following case, not as typical of results that may always be expected, but rather as illustrating, notwithstanding our theories, that no one form of current, or method of application, is exclusively indicated:

Miss T., aged twenty-two, was referred to me, January 11, 1877, by Dr. Geo. A. Peters. The patient was in fair general condition, but had suffered from excessively painful menstruation almost from the first appearance of the catamenia.

She was submitted to general faradization, and after receiving eleven applications, the menses appeared, but were attended with little, if any, pain. Nine more applications were given before the next appearance of menstruation, and with equally good results. In this connection I wish merely to add that while electricity is a mysterious agent, and has, therefore, attracted to it much of ignorance and credulity, there

is nothing mysterious or exceedingly difficult in its methods of application, as has been too frequently implied in the presentation of the subject. Everything well authenticated, and of real value, relating to the *modus operandi* and *rationale* of electro-therapeutics, has been stated over and over again, and is open to all.

A. D. ROCKWELL.

### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from October 14 to October 20, 1877.*

FRANTZ, J. H., Major and Surgeon. Granted leave of absence for two months on surgeon's certificate of disability. S. O. 239, Div. of the Atlantic, Oct. 15, 1877.

BUCHANAN, WM. F., Captain and Assistant Surgeon. Relieved from duty at Allegheny Arsenal, Pittsburg, Pa., and to return to his station, Morgantown, N. C. S. O. 241, Div. of the Atlantic, Oct. 17, 1877.

SKINNER, J. O., First Lieutenant and Assistant Surgeon. Relieved from duty at Carlisle Barracks, Pa., and to return to his station, Fort Johnston, N. C. S. O. 241, C. S., Div. of the Atlantic.

### Medical Items and News.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending October 20, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
Oct. 13.....	1	26	40	2	3	49	0
" 20.....	0	33	42	3	4	54	0

RED CROSS SOCIETY.—The Queen of England has made a donation of £250 for the relief of the sick and wounded of both armies of the East.

HOME HOSPITALS IN ENGLAND.—The idea of establishing Home Hospitals in England meets with much favor, one-fourth of the guarantee-fund having been subscribed.

EXAMINATIONS OF CANDIDATES FOR MEDICAL DEPARTMENT OF U. S. ARMY.—An Army Medical Board will be convened in this city early in November, for the examination of applicants for appointment as assistant surgeon.

The following will be the general plan of the examination:

1. A short essay, either autobiographical or upon some professional subject—to be indicated by the Board. 2. Physical examination. This will be rigid, and each candidate will, in addition, be required to certify "That he labors under no mental or physical infirmity, nor disability of any kind, which can in any way interfere with the most efficient discharge of his duties in any climate." 3. Oral examination on subjects of preliminary education, general literature and general science. The candidate must satisfy the Board in this examination that he possesses a thorough knowl-

edge of the branches taught in the primary schools, and a failure to show this, will end his examination. Oral examination on scientific subjects will include Chemistry and Natural Philosophy; and that on literary subjects will include English literature, History of the United States and General History—Ancient and Modern. Candidates possessing a knowledge of the higher mathematics, the ancient and modern languages, will be examined therein, and due credit given for a proficiency in any or all of these subjects. 4. Written examination on anatomy, physiology, surgery, practice of medicine, and general pathology, obstetrics, and diseases of women and children. Oral examination on these subjects, and also on medical jurisprudence, *materia medica*, therapeutics, pharmacy, toxicology, and hygiene. Few candidates pay the attention to hygiene which it deserves; it is made an important subject in this examination. 5. Clinical examination, medical and surgical, at a hospital. 6. Performance of surgical operations on the cadaver.

The Board will deviate from this general plan whenever necessary, in such manner as they deem best to secure the interest of the service. The Board will report the merits of the candidates on the several branches of the examination, and their relative merit in the whole, according to which the approved candidates will receive appointments to existing vacancies, or to vacancies which may occur within two years thereafter. An applicant failing one examination, may be allowed a second after one year, but not a third. No allowance will be made for the expenses of persons undergoing examination, as this is an indispensable prerequisite to appointment, but those who are approved and receive appointments will be entitled to transportation on obeying their first order.

MARSHALL INFIRMARY, TROY, N. Y.—The number of patients admitted during the year was 219; males, 163; females, 56. Total number of patients under treatment during the year was 268; males, 198; females, 70. Of this number there were cured 131; males, 100; females, 31. Improved, 37; males, 27; females, 10. Unimproved, 24; males, 17; females, 7. Dead, 25; males, 15; females, 10. Total number discharged during the year was 217; males, 159; females, 58. The number of patients remaining under treatment at the close of the year was 51; males, 39; females, 12.

AMERICAN OPTICAL INSTRUMENTS.—It is gratifying to learn that American skill in the construction of optical instruments is beginning to be appreciated abroad. The microscopes of Tolles, Zentmayer, Grunow, and other American manufacturers are winning great favor in Europe, and Alvin Clark & Sons, of Cambridgeport, have just finished an eleven-inch refractor for the Lisbon Observatory. Several other large instruments are in course of construction by this firm, among others a twenty-six-inch telescope for Mr. McCormick, of which the lens is completed. They are about commencing work on a twenty-seven-inch refractor for Yale College.

BELLEVUE HOSPITAL MEDICAL COLLEGE.—Dr. Brown-Séquard will deliver a course of eight lectures at the Bellevue Hospital College, on "Paralysis and Convulsions as Effects of Organic Disease of the Brain." The Profession is cordially invited by the Faculty of the College to these lectures. The days and hours will be as follows:—Friday, Nov. 2, at 2½ o'clock; Saturday, Nov. 3, at 3½ o'clock; Friday, Nov. 16, at 2½ o'clock; Saturday, Nov. 17, at 3½ o'clock; Friday, Nov. 30, at 2½ o'clock; Saturday, Dec. 1, at 3½ o'clock; Fri-

day, Dec. 14, at 2½ o'clock; Saturday, Dec. 15, at 3¼ o'clock.

**HOW LONG OUGHT WOMEN TO STAY IN BED AFTER DELIVERY.**—A valuable paper was read at the last stated meeting of the Medical Society of the County of Kings, September 18, 1877, by H. J. Garrigues, M.D., entitled, "How Long ought Women to stay in Bed after Delivery?" Dr. Garrigues dissents from the positions taken by Dr. Goodell, of the Philadelphia Preston Retreat, recently published in the American supplement to the *Obstetrical Journal*, both on theoretical and on practical grounds. Dr. Goodell, it will be remembered, holds the view that, labor being a physiological process, it should not be made to wear the livery of disease, and that, under circumstances fairly favorable, the patient should be encouraged to get up and dress herself on the third or fourth day after delivery. His reasons are, that the upright posture excites the womb to contract, that uterine diseases scarcely exist among races whose women leave their beds early, and that his own experience has shown him that convalescence is rendered far more prompt and sure. After discussing the literature of the question, as represented by Scanzoni, Naegele, Siebold, Schroeder, Spiegelberg, Cohnstein, Bischoff, Barnes, Playfair, and Gallard, Dr. Garrigues cites the exact investigations of Hecker, Heschl, Boemer, Duncan, Serdukoff, and Autefage, as to the weight and dimensions of the womb immediately after delivery, and the relative rapidity with which the organ resumes its normal weight, dimensions, and position. It appears from Boemer, who has measured in 64 cases, that immediately after the event the length of the organ varies from 12 to 19 centimetres (3½ to 4½ in.), and that at the expiration of two weeks the womb is still from 9 to 12 centimetres long, the length of the cavity in the non-puerperal state being only from 6 to 7 centimetres. The width of the organ at the first examination was 10 centimetres, and its elevation above the symphysis pubis 11 centimetres. The elevation diminished during the first twelve days to 5.2; but on the twenty-second day it was still 4.6, whereas the normal elevation is only 3 centimetres. Heschl's data as to weight are even more significant. The organ, according to Heschl, weighs from 22 to 24 ounces immediately after parturition; at the end of the first week from 19 to 21 ounces, at the end of the second from 10 to 11 ounces, at the end of the third from 5 to 7 ounces; its normal weight of from 1½ to 2 ounces being arrived at only by slow reduction at the end of the second month. Again, the formation of a new mucous lining of the organ never occurs before the third or fourth week, and the regeneration of that tissue is often delayed considerably longer than that; not being finished, according to M. Robin, until sixty or seventy days after the delivery. Dr. Garrigues gives a short but very comprehensive summary of this and other physiological processes, and argues from all the data collected by modern research that the sitting posture is apt to produce alterations in the shape and position of the womb, which hinder free circulation and disturb its involution, to say nothing of tending to form emboli—a frequent cause of sudden death after parturition as well as of dangerous secondary hemorrhage. The time that a woman should stay in bed cannot, he concludes both from physiology and from practical observation, be limited by any prescribed number of days, but must depend upon the rapidity of the shrinkage in weight and dimensions, and of the regeneration of the mucous membrane in each particular case, and these points

the practitioner must determine by daily examination. His rule is not to permit a patient to get up until the womb has retired from the abdominal wall and subsided behind the symphysis, which, in most cases, takes place about two weeks from the date of the delivery.

**MEDICAL ADVERTISING.**—Our esteemed contemporary the *Albany Evening Times*, takes strong ground against the medical advertising monopoly in Albany. After quoting our recent editorial on the subject it remarks as follows:

"Connection with a college or hospital seems to be regarded by some doctors as giving them a privilege to advertise which is denied other doctors who are not connected with such institutions. Indeed, it would appear that the principal advantage of being members of a college or hospital staff is to enable the doctors connected with those institutions to carry out successfully the advertising dodge; while the code or law of the Ophthalmological Society (pertaining to diseases of the eye) forbids its members even to put the word 'oculist' on an office sign. Yet this advertising dodge, under the head of 'hospital clinics,' enables certain doctors to do a brisk business in advertising by keeping their names and their 'wonderful operations' before the public in the newspapers. We had thought that the faculty of a medical school were presumed to stand at the head of the profession, and were supposed to give to the other members an example of integrity and strict honor in obeying the code of medical ethics. The case, however, is so different, that we would suggest to our medical friends the question whether—since certain college professors persist in indirectly advertising—it would not be better to do away with the present code of medical ethics and advertise openly, as other business men do, and pay for their advertising as a simple matter of justice to the publisher and respect for the medical by-laws."

**REPEATING PHYSICIANS' PRESCRIPTIONS.**—Physicians complain that their prescriptions are not only used by their patients, but handed round oftentimes amongst a large circle of friends, and in many instances handed down from generation to generation as a kind of heirloom. This custom has its attendant dangers, and in the case of poisons might be productive of bad results, to remedy which it is proposed in Germany to institute a law prohibiting chemists to make up any prescription containing strong remedies—as drastics, emmenagogues, sedatives, etc.—unless the prescription is again countersigned by the medical man who originally gave it.—*Med. Press & Circ.*

**REMOVAL OF STRONG ODORS FROM THE HANDS.**—The *Schweizerische Wochenschrift für Pharmacie* has a communication from F. Schneider, in which he states that ground mustard, mixed with a little water, is an excellent agent for cleansing the hands after handling odoriferous substances, such as cod-liver oil, musk, valerianic acid, and its salts. Scalpans and vessels may also be readily freed from odor by the same method.

A. Huber states that all oily seeds, when powdered, answer this purpose. The explanation of this action is somewhat doubtful, but it is not improbable that the odoriferous bodies are dissolved by the fatty oil of the seed, and emulsified by the contact with water. In the case of bitter almonds and mustard, the development of ethereal oil, under the influence of water, may perhaps be an additional help to destroy foreign odors. The author mentions that the smell of carbonic acid may be removed by rubbing the hands with damp flax-seed meal, and that cod-liver oil bottles

may be cleansed with a little of the same or olive oil.

**NEW YORK ACADEMY OF MEDICINE.**—At a stated meeting held Oct. 18, 1877, Drs. W. R. Gillette and A. Hodgman were elected Resident Fellows.

**BODY-SNATCHING.**—A medical student of Syracuse has been accused of robbing a grave in the neighborhood of that city, and transporting the body to the dissecting-room of the college. The remains have, despite mutilation, been identified by friends, and altogether, in a legal aspect, the case looks far from promising to the young adventurer.

**UNIVERSITY OF MICHIGAN — MEDICAL DEPARTMENT.**—As a reward for extending the annual course from six to nine months, and grading the same, this institution has increased its number of students, and has proved in a substantial manner that some who wish to become doctors are not willing to do so in the shortest possible time and in the easiest possible way.

**HOME FOR OPIUM HABITUÉS.**—A private medical home for opium habitués has been opened in Brooklyn. The medical attendants are Drs. J. B. Mattison and A. M. Mathias.

**THÈSES DE PARIS.**—Some of the theses presented this year which have attracted attention on account of their merit, were written by female medical students. Those worthy of special mention were by Mme. Ribard, on Eye-Drainage, by Mlle. Ocounkoff, on the Physiological Functions of Sulphuric Ether, by Miss Anna Dahms, on the Histology of the Thyroid Gland.

**FATAL POISONING BY IRISH YEW.**—A case is reported by the *British Medical Journal* of a fatal poisoning by Irish yew, several doses of a strong infusion of which were administered by a man to his wife for the purpose of producing abortion. The widower was committed by the coroner's jury on the charge of wilful murder.

**THE INTERNES OF THE HÔTEL-DIEU, OF PARIS,** have sent a letter to the Administrator of Public Assistance, complaining of the insalubrious character of the apartments destined for their use in the new Hôtel-Dieu. These apartments have no windows, and are damp as well as dark. The contrast between them and the luxury and sumptuousness of the bureaux, and the apartments set apart for the employés of the hospital, is very striking, and is particularly wounding to the pride of the doctors.

**JABORANDI IN MASTITIS.**—Dr. G. M. Wells, of Sonoma, Cal., writes: "Sir:—Allow me to direct the attention of the profession to the use of jaborandi in mammary abscess.

"Mrs. G. has been the subject of repeated abscesses; as soon as one was formed and lanced another succeeded, until she became 'weary and worn out.' Quinine failed, sulphocarbolates did no good, belladonna externally and internally disappointed our hopes, so I determined to try some other remedy and gave the following:

R  
Ext. jaborandi fld.,  
Ext. dandelion fld. . . . . ℥̄ ss.  
Syr. simp. . . . . fl. ʒ̄ ij.  
M. S. ʒ̄ ss. every two hours.

"I directed the above to be used until profuse sweating was produced, which occurred after the third dose in such profusion as to saturate the linen thoroughly, and continued for several hours. As soon as the sweating became thoroughly established the tempera-

ture and pain (which before had been excessive and severe) was reduced and relieved, and the symptoms, which were so threatening the day before, were all gone. The debilitating effect of the sweating passed off in a few days, since which time the patient has been in excellent health. I have had no other opportunity to test the remedy in this class of cases, but have the utmost confidence in its virtue.

**SIZE OF FAMILIES IN COLOMBIA.**—In the State of Antioquia, Colombia, each marriage produces, as a rule, from ten to fifteen children. The mothers all nurse their own children, at least until the ninth month, when the symptoms of a new pregnancy usually present themselves. Dr. Posada-Aranjo knows a woman who has thirty-four children, all living. He also knows a man who has been married three times, and has had fifty-one children. As this man's present wife is still young, he has a chance of increasing the number of his offspring to sixty. The women marry at the age of thirteen, fourteen, or sixteen years. The first menstruation occurs at the age of thirteen or fourteen years.

**MEDICAL SOCIETY OF THE COUNTY OF NEW YORK—OFFICERS ELECT FOR 1877-1878.**—At an annual meeting held Oct. 22, 1877, the following officers were elected: President, Dr. John C. Peters; Vice-President, Dr. Isaac E. Taylor; Rec. Secretary, Dr. A. E. M. Purdy; Cor. Secretary, Dr. F. A. Castle; Treasurer, Dr. H. P. Farnham; For Censor, Dr. H. G. Piffard; For Delegates to State Medical Society, Drs. R. W. Taylor, D. H. Goodwillie, L. D. Bulkley, and G. H. Fox.

**THE PETRIFICATION OF BODIES.**—Much curiosity is felt by those opposed to the present custom of burying the dead, with regard to the results of the system mentioned by Gorini, of Lodi. This genial man proposes to prevent the putrefaction of the body by petrifying it. His experiment with Mazzini has proved entirely successful. All who have visited the great republican in his tomb have been astonished at the perfectness with which his traits have been preserved in the petrified body. Gorini keeps his method of petrifying bodies secret, but has taken measures to secure its publication after his death.

**PROF. C. VON HEINE, of Prague,** died of diphtheria last month. Prof. von Heine was one of the foremost surgeons in Germany, and was, moreover, a man of such purity and amiability of character that his death will be widely felt and deplored.

**THE MALPRACTICE CASE IN BROOKLYN.**—We are pleased to state that the charge of malpractice against Drs. Geo. K. Smith and J. Byrne, of Brooklyn, for improperly amputating a cervix uteri, was not sustained, and a nonsuit was granted. The damage was laid at the modest sum of twenty-five thousand dollars to offset a bill for services rendered, which the plaintiff refused to pay.

**BEGINNING OF MENSTRUATION.**—Dr. Parvin, editor of *American Practitioner*, tabulates one hundred cases of menstruation, and concludes that the average age of its commencement is thirteen years and eight months; and the average duration of flow four days and six hours.

**INDIAN FAMINE.**—The extremest stress of the Indian famine is at an end, and the people engaged on the relief are beginning to hurry away to their homes. Copious rains have fallen over the stricken districts.

## Original Communications.

### LISTER'S ANTISEPTIC TREATMENT OF WOUNDS.

THE MATERIALS USED AND THEIR MODE OF APPLICATION.

(Being a Report to the Surgeon-General of the U. S. Army.)

By A. C. GIRARD, M.D.,

CAPTAIN AND ASSISTANT SURGEON U. S. ARMY.

**GENERAL:**—I have the honor to transmit herewith a report on the materials used in Lister's system of wound-treatment and their mode of application.

It is not necessary for my purpose to enter into a discussion on the yet undecided question of the *modus operandi* of the antiseptics, and I may therefore leave to other pens the task of elucidating, from the testimony extant, if the bacteria are the only causes of putrefaction—if there are different species of them, some harmless, some injurious,—if they act mechanically or as a poison—if they can cause putrefaction in normal tissues or need a pathological focus for their functions, or simply act as a ferment under certain circumstances, or are bearers of a "septic zymoid." The only thing which concerns us here is the indisputable fact that there *are* germs or ferments in the atmosphere which will produce putrefaction in wounds, and that by preventing their ingress we can, in most cases, avert the complications which cause the greatest fatality in surgery. This is the key to Lister's system. For the sake of science it is to be hoped that, sooner or later, more light will be thrown on the physiological and pathological changes connected therewith. This will, however, not necessarily benefit suffering mankind, and we cannot wait for it and shut our eyes to the remarkable clinical results attained by Lister and his followers, because they cannot be explained to everybody's satisfaction. Be the "germ theory" true, or partly true, or an absolute mistake, practically it matters not; for the present it is the best explanation we have for a most successful method and the best guide in its use.

It would unnecessarily extend the size of this report should I attempt to relate the steps by which Mr. Lister gradually introduced and perfected the system of wound-treatment which I am about to describe. He first used it in his hospital in Glasgow in 1868, but ever since it has gradually been changed and improved on by him, and will probably undergo further changes in time. It has met with much indifference and with many enemies, but is gradually working its way into all the great hospitals of the civilized world.

During a sojourn abroad last winter, my attention was particularly drawn to this innovation in surgery, as it had been introduced on the European continent but two years, and was the almost exclusive topic of conversation of the surgical profession there. It happened that my first intercourse was with some of the most decided and renowned opponents of the system, and I became acquainted with all the objections to it before I had witnessed its advantages and benefits. I received therefore the glowing accounts of Lister's disciples with an incredulous ear, and it was only by travelling from one "Lister hospital" to another that belief in its superiority forced itself upon me. I became convinced that if it is not the only proper wound-treatment, it is the safest one, and renders conservative surgery possible beyond what had ever been believed. It would take volumes to describe all I witnessed, and

I cite but a few examples. Who, before this, would have fearlessly opened the knee-joint for suppurative arthritis, as I saw done under the "spray," the patient recovering in a few days with a sound joint? Who would have expected an ovariectomy with general adhesions, in a woman of seventy-five, to heal in eight days without a symptom of reaction; or a laparotomy for the liberation of incarcerated peritoneal hernia, in a moribund patient, healing in six days; or a resection of the ulna in nine days? I observed several hip-joint resections recovering in the most favorable manner, numbers of compound fractures of the extremities knitting under Lister's dressing like simple ones; even comminuted fractures which formerly would have induced removal of the limb, united without an unfavorable symptom. Cancers which had been removed with great loss of substance united by first intention; other tumors were extirpated and the operation caused no more inconvenience than a simple incision. The smell of putrefaction was banished from wards where scores of patients were lying with grave injuries and severe wounds. Hospitals which had been in use for centuries, and had become hot-beds of infection, where the majority of operations formerly were followed by pyæmia, gangrene, and erysipelas, where everything had been tried to combat these evils, where treatment "open," "occlusive," by "immersion," compresses of chlorine water, carbolized water, salicylic acid, even Lister's "gauze" and "paste" had failed, became entirely free from these complications as soon as Lister's system with *all* its precautions had been introduced. Professor v. Nussbaum, Surgeon-General in the Bavarian Army, told me that formerly he operated in his hospital with the greatest reluctance, as nearly every case was sure to be followed by grave accidents, even the opening of a paronychia or the amputation of a finger would cause pyæmia and death; wounds granulating in the most healthy manner, as soon as brought into his hospital, would become gangrenous, and the patient would die, when a few days before he appeared to be on the eve of entire recovery. Now everything is changed. While during sixteen years, in which he had charge of the Munich General Hospital, pyæmia never failed a single month to make its appearance, until at last it seized eighty per cent. of the patients, since the introduction of Lister's system it has absolutely disappeared. The same is the experience of Professor Volkmann in Halle. These are extreme cases, but they prove the more palpably the advantages of antiseptics. Other hospitals of more recent construction and less infection showed, of course, a lesser rate of improvement; but there, also, the rapidity of recovery and entire absence of complications were sufficiently plain proof to induce the surgeons to carry out the system with all the care observed in infected buildings. It has even found its way into private practice, and is used there also with great success.

It is difficult to adduce statistics in favor of a particular system without going into details which would carry me beyond the scope of the present paper. A few examples might perhaps suffice. While in amputations of the thigh we find a usual percentage of deaths of from 76 to 92, we find in the hospital of Professor Volkmann that six consecutive operations of this kind, and one exarticulation at the hip-joint, recovered. Of twenty-seven consecutive amputations, of forty consecutive compound fractures, all recovered. Which other system shows like results? Before the introduction of Lister's system, Professor v. Nussbaum performed thirty four ovariectomies with sixteen deaths (47 per cent.); since then, he made the same operation sixty-two times and lost only twenty-one

patients (34 per cent.)—of the last eight none. Lister's percentage of deaths during the two years preceding introduction of his system was 35, during the three succeeding years 15.

My personal investigations and studies were made with German surgeons, some of whom had become familiar with the system under Mr. Lister's personal supervision. Time and other plans prevented my visiting Edinburgh. In fact, I did not have the intention of pursuing this particular line of study abroad until it was forced upon me by the marvellous results I witnessed.

The purpose of this report is to communicate, in the simplest manner possible, the materials used in this mode of wound-treatment, their mode of preparation as applicable to our resources in the service, and the technical peculiarities of the dressing.

*Lister's system is not the application of peculiar dressings or the use of particular antiseptics.* It is a method of treating wounds based on the "germ theory," and its principal aim is to prevent the entrance of germs into wounds, to destroy them if already there, and to guard against the accumulation of wound-secretions. In order to attain this end he surrounds the patient with a series of precautionary measures, which have from time to time been improved on by him. These require peculiar materials and appliances, of which I present the latest phase that came under my observation. They are enumerated without particular plan. Where the mode of preparation is not indicated, it will suggest itself; where it is described it is adapted as much as possible to self-preparation, thereby facilitating the introduction of the system by diminishing its greatest objection—the cost. Their use is described as concisely as possible, and will become clearer when I shall treat of the mode of operating and dressing.

1. *Carbolized Solution (Acid)*, carbol. cryst. 5, aq. 100) is used to clean the neighborhood of wounds before operation, to disinfect the hands of surgeon and assistants, and instruments, to wash out septic wounds and clear drainage-tubes.

2. *Carbolized Water*, a 2½ per cent. solution of crystallized carbolic acid in water. It is used in the spray and to wet the "lost gauze."

3. *Carbolized Oil (Acid)*, carbol. cryst. 5, ol. oliv. 100), to oil catheters or other instruments, or fingers when about to be introduced into some of the cavities. It is also employed when a constant direct contact of the antiseptic with the wound is necessary, as in caries, or where the gauze dressing cannot be applied, as in abscess of the rectum.

4. *Solution of Chloride of Zinc* (8 per cent.), 1 part of liq. zinc. chlor. mixed with 3 parts of water. Where wounds have been exposed unprotected to the access of atmospheric air, or where, from mistake in dressing, aseptic wounds have become septic, they are swabbed out with this solution. It is more effective than carbolic solution, but too powerful for permanent use in the dressings.

5. *The Spray*. In order to prevent the entrance of living germs, during an operation or dressing, a spray of "carbolized water" is directed on the wound. The best instrument for this purpose is "Lister's spray," a steam atomizer which throws a large cone of finely divided spray. It is almost indispensable in long operations and where a considerable space of tissue is exposed. In its absence it may be replaced by the ordinary steam atomizer, of which two ought to be at hand, as they are sooner exhausted. Their suction tube is unnecessary, and a glass tube, drawn to a fine point, and bent at an acute angle, to throw the steam

against wounds without necessity of tipping the instrument, may take its place. In the absence of these, or for short dressings, Richardson's spray apparatus may be used. It has, however, serious defects; it gives out frequently without apparent cause, is very fatiguing, and wets the wounds too much, as the spray is not as finely divided as that of the steam atomizer.

6. *The Protective* is oiled silk, coated with copal varnish, to render it impermeable, and then covered with a thin layer of 1 part dextrine, 2 parts starch, and 16 parts "carbolized solution," to facilitate adhesion of the disinfecting fluids into which it is dipped before being applied to the wound. The purpose of the "protective" is to prevent the irritating effect of the contact of the antiseptic with the wound. It is placed immediately over this, overlapping it but little.

7. *The Antiseptic Gauze*, a peculiar unstarched cotton gauze, selected by Mr. Lister on account of the facility with which secretions penetrate its meshes. It is prepared with antiseptics, and thus, after absorbing the wound fluids, it prevents their decomposition. Pieces of cotton gauze, six yards in length and one yard in width, are to be placed in a zinc trough and heated in the water-bath for several hours, after which they are spread out and a hot mixture of one part cryst. carbolic acid, five common resin and seven paraffine is poured over them by means of a syringe. They are then returned to the trough and submitted to pressure for some hours, to cause an even distribution of the fluids. The resin is to hold the carbolic acid more firmly, and prevent it from being washed out or evaporated too quickly. The paraffine diminishes adhesion of the dressing. This gauze is prepared in factories in Germany, the best known being the "International" factory, at Schaffhausen, Switzerland. Its great cost (20 cents a yard in the factory) is a considerable drawback. I have, therefore, tried to replace it by cheaper material, and to prepare it myself, and have successfully used old mosquito netting for this purpose. As this is really the only part of Lister's dressings for which the Army Supply Table does not furnish the materials, it may be of interest to learn how it is done. Old mosquito bars, which have become useless for their legitimate purpose, are steeped, or, perhaps better, foiled in lye, to remove all dirt and render them more hygroscopic. They are then immersed in the hot resin mixture, which may be heated in a tin bucket on the stove. To remove the surplus liquid they are passed through a clothes-wringer, allowed to cool, stretched into shape, and put away in a closed vessel or wrapped up in oiled muslin. The clothes wringer is easily cleaned with boiling water and a cloth. I have used this antiseptic netting with the same results as the imported gauze.

The gauze is used wet with carbolized water in immediate contact with the "protective," folded in about six thicknesses and overlapping the "protective" several inches. The remainder of the gauze is applied dry. Lister considers eight layers, *largely overlapping* the wound, sufficient. Between the seventh and eighth layers he inserts the "McIntosh."

8. *The McIntosh*, common rubber cloth, is used to keep the secretions of the wound from finding their way immediately to the surface, and to compel them to permeate the whole dressing, thus being constantly in contact with the carbolic acid. It is cut an inch smaller than the gauze, that the secretions when about to appear externally may be discovered, while yet lying in antiseptic material. The "McIntosh" need not be renewed with the dressing, but may be washed off with carbolized water and used again.

*Catgut* is the *sine qua non* of Lister's dressing for ligatures and deep sutures. In a few days it is absorbed and the wounds close over it without danger of its acting as an irritant or permitting hemorrhage. In order to prevent its becoming soft, spongy, and slippery, it has to go through a process, by which it is rendered tough, flexible, and able to resist the action of the wound secretions for a sufficient length of time. It is first shaken up in a carbolized emulsion of one part cryst. carbolic acid (dissolved by addition of 10 per cent. water) and five parts olive oil. It should then be no more disturbed, but set aside in a cool place. The catgut should be kept separate from the watery part of the emulsion. This is most conveniently done by placing a sufficient number of pebbles into the vessel containing the emulsion to support a small disk of glass out of reach of the water, on which the coils of catgut are laid. It takes at least two months before it acquires the necessary qualities. The catgut is used in different sizes, from the thickness of a horsehair to that of twine.

10. *Salicylic Cotton*. Mr. Lister has of late used this to bolster up and fill inequalities of the surface. The salicylic acid not being volatile, and cotton easily impregnated by it, it forms a useful supplement to the gauze. It is prepared by first removing the fatty matter of the cotton, by boiling it in lye or other alkaline liquid. Thus the cotton becomes hygroscopic, which quality may easily be tested by throwing a small ball on water. In its natural state it will not sink,—if prepared it will go to the bottom of the vessel in a very short time. The proportions are about 8 oz. of the acid, 8 oz. alcohol, and 2 gallons of water. The addition of about 20 per cent. of glycerine is said to prevent the disagreeable dusting of the acid.

11. *Sponges*. All sponges used in connection with Lister's dressing, in the cleaning of wounds and absorption of wound-secretions, should be prepared in the following manner: After being carefully beaten, cleaned, and washed out in lukewarm distilled water, they are immersed in the "carbolized solution," and kept there until needed. After use they are washed out in the solution and replaced in the vessel. In this manner they can be used over again as long as they last. In addition to the usual small dressing sponges some larger ones are to be kept on hand. They are applied to wounds the first day after the operation, to absorb the more copious secretion caused by the spray.

12. *Drainage-Tubes* are small flexible rubber tubes, of the size of a small quill to that of a little finger, with numerous openings on the sides, each of half the diameter of the tube. Their use is to facilitate the egress of wound-secretions without interfering with union. One or more are introduced, according to the size and number of angles of the wound, reaching to the bone. They are secured to the skin by a thread drawn through their extremity and fastened by a strip of isinglass or a small safety-pin. They must be cut on a level with the skin, as otherwise the pressure of the dressings will obstruct their lumen. In places where the slippery rubber tube is not easily retained, as in the anus, some lint dipped in carbolized oil might take its place. Of late Mr. Lister adds to the rubber tube several threads of catgut. The tube is removed in a few days, the catgut assisting in the drainage as long as it is necessary and is then absorbed, the outside parts falling off.

13. *Antiseptic Silk*. The catgut is only used in ligatures and deep sutures. For superficial sutures it does

not retain its firmness long enough, and silk is preferred in its stead. This is rendered antiseptic by being steeped for an hour in a hot mixture of bees-wax ten, cryst. carbolic acid one, and then drawn through a cloth to remove the surplus wax. It is then preserved in a closed vial. In this manner it combines the advantages of the wire with the suppleness of the silk. Septic germs cannot penetrate in the interstices of the fibre, and the wax, besides increasing the hold of the knot, retains a sufficient amount of the antiseptic to destroy any germs which might enter the suture.

I might here, also, mention a method introduced by Mr. Lister to approximate the edges of the skin where from loss of substance this would be difficult, if not impossible, by superficial sutures, as in cancer in the breast when a part of the skin is implicated and has to be removed. A piece of annealed or silver wire is passed through the whole thickness of the flap, some two or three inches from its free edge, and brought out on the opposite side at the same distance. The ends of the wire are fastened over a small lead plate; thus sufficient force can be used to cover almost any deficiency. As many of these wires may be applied as the size of the wound may necessitate. The superficial sutures are then introduced, and a union by first intention may be looked for. The secretions of the wound pass through the drainage-tube. Whenever the neighboring integument seems to have accommodated itself to the strain, the wires are removed by cutting them at one of the plates. I have used this once, with success, after removal of a tumor of the scalp, with a circular loss of skin of two inches diameter, and obtained union *per primam*.

In order to complete the list of dressings pertaining to Lister's system, I must add the preparations of boracic acid, which is claimed to be an antiseptic, milder than carbolic acid, but holding its properties longer.

1. *Boracic Water* (3½ per cent. solution of boracic acid in water). The boracic acid is obtained from borax by decomposition with sulphuric acid. The water is mainly used to moisten the boracic lint, where this is employed.

2. *Boracic Lint* is prepared like salicylic cotton, which will be mentioned hereafter. It takes the place of carbolized dressings, where these cannot be closely adapted to the skin, as in resection of the lower jaw and in hare-lip sutures.

3. *Boracic Ointment* (Acid borac., *cera alb.*, of each 10, ol. amygd. dulc., paraffine, of each 20, fiat ungt.) This is used spread on thin cotton and applied to ulcers and granulating surfaces. It is neatly fastened to the skin by painting the edges over with collodion. I have seen it used with success after ablation of epithelial cancer of the face.

In applying Lister's dressings it must be borne in mind that they promise complete success only in operations where the prescribed precautions for destruction of germs, or prevention of their entry into the wound, have been conscientiously observed. Even the most careful disinfection of wounds which have been exposed unprotected will not always be successful, as germs may have penetrated beyond the reach of the antiseptic. Still even there the probabilities are in favor of antiseptics, and the facility of evacuation of pus by the drainage-tubes, and its disinfection in the meshes of the gauze, which also prevents the entrance of new living germs, predisposes most wounds to rapid healing. We must at all times be thoroughly alive to the fact that the entrance of *one* living germ may destroy the usefulness and render an operation, which otherwise would barely affect a pa-

dent's health, the starting-point of erysipelas, gangrene, or pyæmia. These germs may be introduced by the surgeon's finger, by the instruments, by the very dressings, if any one of Lister's minute directions is neglected. On the other hand, if once a surgeon and assistants understand the system thoroughly, it is the easiest mode of operating and dressing; the rules are so positive that surgery loses its speculation, and a quick recovery can almost with certainty be looked for. A surgeon in one of the large German cities told me he followed Lister's system, but did not get the vaunted results. He invited me to witness a small operation which he was going to perform "under Lister." It explained to me his want of success. While he thought he followed Lister's rules rigidly, he committed nine grave faults, each of which would nullify their benefits. Still, in case of failure, he would have claimed that he failed in spite of following Lister. Such adherents are his worst enemies. The importance of the lesson may excuse this anecdote.

Whenever elevation of temperature, rapidity of pulse, erysipelas, swelling, diffuse cellulitis, symptoms of pyæmia follow an operation, we may be sure that in nine cases out of ten some fault has been committed—either the discharge has appeared on the surface and been allowed to become septic, or the drainage-tube is closed, or not properly trimmed, or not introduced to the proper point.

The following articles, as a rule, should be at hand before proceeding to an operation: Towels, soap and sponge with warm water; nail-brush and ether; two bottles carbolized water; two atomizers, filled—the second in case the first should fail; basin, with the necessary small sponges, and one or two large ones, soaked in carbolized solution; bottle with the chloride of zinc solution; basin with carbolized solution, to disinfect the hands of surgeon and assistants—the instruments and a piece of gauze should also be kept in this basin; vessel with catgut; vessel with drainage-tubes; bottle with antiseptic silk; and the necessary gauze and McIntosh.

First of all the hair in the vicinity of the place to be operated on must be carefully shaved off. The skin is then to be cleaned with soap, water and a nail-brush, and after that with ether, to remove fatty matter and detritus. The patient is then etherized. Here I must mention that in almost all cases *chloroform* is used in Germany as an anæsthetic, and in a most fearless manner, even for a painful dressing. I was informed by several distinguished surgeons that they never had a death from chloroform in thousands of operations. It is true they had, at times, cases of partial asphyxia and collapse, but never failed, by persistent efforts, to revive the patient. One case was related to me where attempts at resurrection were continued for four hours on a patient to all appearances dead; the heart was, during that time, incited to a feeble action by means of electricity on the phrenic, and slight blows in the precordial region. He finally recovered. I may be pardoned this digression in view of the now general crusade against chloroform in this country.

As soon as the patient is thoroughly anæsthetized the spray is set in operation. Should one of the extremities be the suffering part, Esmarch's bandage and tourniquet are applied in almost all cases. The only exception I know of is where extensive suppuration is going on in the limb, when purulent matter might be forced into the circulation. In that case the limb is simply elevated and a tight tourniquet applied some distance above the seat of operation. The advantages

of Esmarch's bandages are too well known to need repetition.

A final washing with carbolized solution is now given to the skin, and the spray is made to play on the wound, taking care not to allow the hand of the operator to intervene. The instruments are taken from the basin as needed, and returned to it as soon as used. The blood is cleared away by the antiseptic sponges. Blood-vessels are secured with the usual forceps and ligated. The ligation in operations performed by the "bloodless method," is done before removing the tourniquet. The place of the large vessels is well known, the small ones are usually found at the intersection of the muscles. The ligation is done with the catgut, care being taken not to use too thick a cord for small vessels, and to make a reef-knot. The two ends are cut off close. The ligature is absorbed or passes off with the discharge, if there is any. Numberless experiments have shown that catgut, if prepared as mentioned above, does not relax until a safe thrombus is formed.

Should, at any time during the operation, the spray cease to work, then the piece of gauze which lies ready in the carbolized water, is to be thrown quickly over the wound, and kept there until the spray is again in proper condition.

The operation being completed, the tourniquet is removed. We may always expect copious parenchymatous bleeding, partly owing to reaction after the elastic bandage, partly because the spray prevents, in a measure, the formation of clots. Arteries which have been overlooked during the previous ligation must now be secured; the rest of the bleeding can easily be stayed by compression or application of cold. The wound is then carefully washed out with carbolized water, no union of the edges is to be attempted until all hemorrhage has ceased. The drainage-tubes are then to be introduced and the superficial sutures applied with antiseptic silk. The personal tact of the operator will show him where and how many drainage-tubes are necessary to facilitate the egress of the discharge. They should in all cases be first dipped in carbolized solution.

The wound is then covered with the protective, dipped in carbolized water, and over this by the lost gauze, that part of the gauze which is applied wet, as described above. Now the spray may be suspended, and the remainder of the gauze is applied.

Here I must digress to show the mode of dressing in wounds which were not made under the spray; after this the dressing is alike in all cases. In fresh wounds it is mostly sufficient to wash them out thoroughly with the carbolized solution. This must be done even in wounds of joints. Where suppuration has already commenced, there the carbolic acid is not sufficient to enforce aseptis. In these cases Lister uses the solution of chloride of zinc, with which the wound is carefully swabbed out. It should be forced into every recess by the pressure of the fingers. Still such cases are always doubtful, and if they do not result favorably the dressing is not always to blame, as the germs may have penetrated beyond the reach of the antiseptics.

We proceed now to the final dressing. A large antiseptic sponge is laid over the protective, and over it the *lost gauze* and the eight layers of gauze, the whole retained in place with broad gauze bandages, cut from the same material. They adapt themselves better than ordinary bandages, do not slip as easily, and have, also, antiseptic properties. A gentle, but firm, compression by them will facilitate the agglutination of the wound-surfaces and the egress of the

discharge. The turns, especially where they are apt to be displaced, must be secured by small safety-pins. Inequalities of the surface, where the gauze does not closely adhere to the skin, must be filled with salicylic cotton, as such places are favorite passages for the wound-secretions.

The first dressing should be removed, at the latest, in twenty-four hours, sooner if the discharges appear anywhere on its surface. The changes are made under spray, which is carefully directed towards the wound, while pins, roller, gauze, sponge, and protective are successively taken off. The protective will be found to have preserved its natural color, if the wound is aseptic. Where decomposition is going on, it shows dark, brownish spots, caused by the action of liberated sulphur in the pus upon the lead of the oiled silk. In this manner it is a delicate test of the success of the antiseptics. Whenever the protective is discolored, the wound must be treated like a septic wound, either with carbolized solution or the chloride of zinc. The spray is to cease as soon as the lost gauze covers again the protective. The changes have to be daily ones as long as the secretions are plentiful. The wound should be interfered with as little as possible—the surroundings being gently cleaned with salicylic cotton or a sponge. If, as usually happens, the surface of the wound closes *per primam*, then two or three dressings will be sufficient. Besides the feelings of comfort or discomfort of the patient, and the staining of the dressing, we find the best indicator as to the necessity of changes in the temperature of the patient's body. Where this is normal, and the bandage unsoiled, we can pass on—everything is right. When the patient's temperature-plate shows an increase over the preceding observation, it will be an absolute indication to remove the dressing and examine the wound. In almost every instance we will find an accumulation of pus, which had not been reached by the drainage, or the tubes are choked, or some slight neglect had permitted some septic changes as shown by the spotted appearance of the protective. A longer drainage tube, a counter-opening with a new tube, syringing with carbolic solution, will remedy the evil, and the temperature falls. The precautions must not be relaxed until the cicatrix is fully formed; a single unprotected granulation has given rise to violent erysipelas.

In conclusion of my remarks on the precautions necessary in the application of the dressings, I wish to state that the paraphernalia of the system are not as intricate and formidable as they appear on paper. In a few days they will become second nature, not only to the surgeon, but to the nurses, even to the patient; the latter will not fail to call attention to the appearance of a stain, and the nurses will no more hand a dressing-forceps without first dipping it in the antiseptic.

This report would be incomplete without the description of a modification of Lister's dressings introduced by Professor Thiersch, in Leipzig. It consists, mainly, in the use of salicylic acid in place of the carbolic. Since the discovery made by Professor Kolbe, that salicylic acid can be cheaply prepared by the action of carbonic on carbolic acid, it has become available as an antiseptic. It is said to have the same properties as carbolic acid, without its irritating effects and unpleasant odor. The results attained by Thiersch seem as good as those of the carbolized dressing, and the method deserves a trial, especially as it combines with other advantages that of cheapness. In place of the gauze, Thiersch uses salicylic cotton; for the spray, salicylic solution (1 in 300);

the same for washing of wounds and immersion of the sponges. The instruments are, however, oxidized by it, and should be kept in carbolic solution. The protective is not necessary, as the dressing is not irritating, and may be replaced by a piece of carbolized gauze. He uses two kinds of salicylic cotton, of which the following is the mode of preparation:

1. *Three per cent. salicylic cotton.* Six ounces of salicylic acid are dissolved in one gallon of alcohol, of 0.830 specific gravity, and the whole diluted by the addition of nine gallons of water, of a temperature of 150 Fahrenheit. This is sufficient for twelve pounds of hygroscopic cotton. (Cotton is made hygroscopic by boiling it in lye.)

2. *Ten per cent. salicylic cotton.* Eight ounces of salicylic acid are dissolved in two and a half quarts of alcohol, of the same specific gravity as above, and this diluted with four gallons of water, of 150 Fahrenheit. This is the quantity prescribed for five pounds of hygroscopic cotton.

It is recommended not to immerse more than five pounds of cotton at any one time, in order to have the solution evenly absorbed. After the cotton is soaked through, under a slight pressure, it is piled up (not hung) to dry. The ten per cent. cotton is usually dyed with carmine to distinguish it from the other.

An inch layer of ten per cent. cotton, and over this two inches of three per cent. cotton, are to cover the wound, held in place by gauze bandages. Such a dressing, according to Thiersch, may be left unchanged for a week, by taking care to cover soiled spots with fresh cotton. One or two dressings are said to be sufficient in ordinary cases. Should the patient complain of the tightness of the coverings, they are simply slit open and another bandage applied over them. Increase of temperature, or pain, necessitate a change, as probably retention of pus has taken place. After a week or two the drainage-tubes may be removed, and a dressing applied which will not require change until complete recovery. When a wound is filled with coagula, or in complicated fractures, in large wounds, and in progressive suppuration, Thiersch uses a slight covering of salicylic cotton and applies irrigation with salicylic water, the skin being protected by imunction with palm oil. As soon as the wound assumes a healthy action he changes to the dry dressing. Of late, finding that the egress of wound-secretions was apt to be choked by the cotton immediately surrounding the wound becoming loaded, he advocates the superiority of a kind of hemp, the fiber of a species of *corehorus*, cultivated in Bengal. It is used in commerce for the preparation of mats. Its advantages are, that it absorbs with more facility and is cheaper than cotton. For surgical purposes it is prepared like salicylic cotton.

In concluding this report I must recapitulate its plan, in order that omissions may not be imputed as oversights, and absence of proof as weakness of argument.

I commenced with a sketch, made as concise as possible, of the manner in which I was convinced of the advantages of Lister's system. I had to abandon the idea of giving clinical proofs to convince others, as, in order to have them above criticism, they had to be too elaborate for the intended size of this paper. But it must be remembered that my views concerning Lister's system are by no means isolated or confined to his immediate pupils; they are shared by men of high standing in surgery, like Nussbaum, Thiersch, Socin, Volkmann, not to speak of his English adherents. The advantages of the method are, consequently, sufficiently vouched for to entitle it to trial. The second

part of this paper is designed to facilitate this trial, by describing the materials necessary, the mode of their preparation, and their application. I must again insist that the technical difficulties cannot be surmounted in a day, and a novice will rarely succeed in maintaining complete asepsis. The more he and his assistants become experienced, the simpler the method will appear, and the more success will be assured. The results will amply repay for a little additional pains.

I cannot close this report without expressing my gratification at the reception extended to me abroad, as a member of the Medical Corps of the United States Army, and the facilities given for investigation. I am especially indebted to Professor v. Nussbaum, Surgeon-General in the Bavarian Army, and his able assistants, Drs. Lindpaintner and Winter, for a great deal of practical information.

The sources used in preparation of this paper are Mr. Lister's Lectures, as reported in the *London Lancet*, and the British and Edinburgh medical journals; an article of Professor Thiersch in Nos. 84 and 85 *Sammlung klinischer Vorträge* of Volkmann; an article of R. Volkmann in No. 96 of the same; an article of A. W. Schultz in No. 52 of the same; a report on the surgical clinique in Munich by Nussbaum; a similar report by Dr. Lindpaintner; a similar one on the clinique in Würzburg by Dr. Angerer. I have, however, mainly relied on personal notes and recollections.

FORT RANDALL, D. T.

## Original Lectures.

### ON THE DIAGNOSIS AND TREATMENT OF HEADACHE.

BEING CLINICAL REMARKS MADE

By WM. H. THOMSON, M.D.,

PROFESSOR OF THERAPEUTICS AND MATERIA MEDICA IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

[Reported for THE MEDICAL RECORD.]

GENTLEMEN:—The history of the case before us is as follows: Two weeks ago to-morrow this man was obliged to cease work on account of a severe headache. The pain continued throughout the entire twenty-four hours, but was rather worse in the afternoon. It was so severe that he did not sleep well. He had no nausea; there was no disturbance of vision, and he never had a headache which prevented him working, until the present attack. You will notice that his face presents a peculiar yellowish tinge; he is slightly jaundiced. The yellowish streaks run off from opposite angles of the eyes, and similar lines run towards the mouth in a manner peculiar to malarial jaundice. He lives in a malarial region, but has not had well-defined intermittent fever. There is no evidence of specific disease.

#### HEADACHE AS A SYMPTOM.

Headache is a symptom and not a disease. The difference between a symptom and a disease is simply this: disease means a morbid condition, while a symptom is evidence of the presence of that morbid condition. The one, however, is frequently mistaken for the other. Pain, at all times, is a symptom, and never a disease. Because headache is a symptom, do not undertake to prescribe for it alone. You will fre-

quently be called upon to prescribe for a headache, but you should remember that it may be a symptom of a large number of different conditions of the body, and should not be the only thing aimed at when remedies are ordered for its removal.

Although headache may be a symptom of so many conditions, there is a way to classify them. *First*: We have headache which is due to *organic* trouble. In a great majority of cases, however, headache is not due to organic trouble, but is of a functional character. A functional headache is never steady; it rarely lasts more than twenty-four hours, and its visits are occasional, so that it is marked by perfect intermissions, no matter how frequently it recurs.

One of the striking features of an organic headache is, that there is a continuous sense of discomfort about the head, although the intense severity may at times be modified. You should, therefore, when a patient comes complaining of headache, first determine whether it is organic or not. There may be an intermediate class of cases between those in which the headache lasts only a few hours or a day, and those in which it is a symptom of organic trouble. These are the cases in which the headache is due to some specific fever, such as diphtheria, measles, small-pox, typhus, etc., or else to malarial poisoning. Such headaches are immediate between the functional and the organic. How are we to distinguish the headache dependent upon specific fever from the other varieties? It differs from the functional in the fact that it is more prolonged. The headache of a specific fever is also accompanied by rise in temperature. It is frontal, and that is the characteristic of the headache of any one of these specific fevers.

Now, if a man comes into your office and says he has had headache steadily for four or five days, that he never had it before, look at his eyes to see whether they are suffused or not. They will usually be suffused, if the headache is a precursor of fever. Again, the headache is in the frontal region, and radiates across the top of the head, but is not usually felt behind. Then you will take the temperature and the pulse, which will probably enable you to determine whether or not the headache is symptomatic of some specific fever. In typhoid fever the pulse may remain normal for two weeks, and yet the case prove to be a severe one; in the other fevers this is not the case.

The other intermediate variety of headache is the malarial. This headache may continue from ten to fourteen days—even longer; it does not, however, usually last longer than two weeks. If this is the case, how are we to determine whether it is malarial or not?

As a rule, malarial headache either *remits* or *intermits*. It always sets in suddenly. It often commences at a certain hour of a certain day, and at the same hour of the following days it is more severe than at any other time within the twenty-four hours. A true malarial headache is as violent at its commencement as at any time during its course. In a large proportion of cases there will be times when the patient has either decided chills or chilly sensations. There may be nothing more than the hands getting cold previous to the occurrence of the headache. It is usually frontal and sometimes felt on one side only.

But you may ask the question, is it not possible that the patient has organic headache?

In the first place, what do we mean by the term organic headache?

It is a headache dependent upon some organic change affecting the brain or its membranes, most commonly the dura mater. As a rule, it is exceedingly

violent. When you are called to see a patient who is suffering from a steady, violent pain in the head, so severe that at times he cries out on account of its severity, the presumption is that it is an organic headache. There are no headaches which will give you such examples of overwhelming agony as some of these cases. The pulse, if irregular, is a valuable confirmation of the diagnosis.

A steady, violent headache, therefore, is one of the most prominent signs of organic headache, and I know of no way in which to remove it, except by the use of the iodide of potassium.

It matters not what the cause is; it may depend upon the presence of a tumor of the brain, or upon organic change taking place in the membranes of the brain; but do not use anything else until this remedy has been carried to the point of tolerance. You will know that the point of tolerance has been reached when the peculiar symptoms of iodism indicating an overdose of the remedy have been developed, and it may require thirty grains, or it may require three hundred grains daily in order to bring the patient up to this point. Iodide of potassium is of little or no use in the treatment of any other form of headache. You will often greatly assist the action of the iodide by a dose of ten to fifteen drops of *ext. conii fl.* and twenty drops of *ext. ergotæ fl.* Syphilitic headache, although organic, is not usually so violent or agonizing as in the case of tumor, by nocturnal exacerbations. It is often surprisingly relieved by mercury administered in a peculiar manner. Rub up one grain of calomel with sugar and divide it into *thirty* parts. Drop one of these powders on the tongue every ten minutes. Suppose, however, we have to deal with a malarial headache; the case before us, doubtless, belonging to that variety, how shall it be treated?

If you are called upon to prescribe for the relief of a symptom indicating mere functional derangement, avoid, if possible, the administration of more than one dose of medicine for that purpose. For example, we will order for this man twenty grains of quinine, to be taken about one hour before the expected increase in the severity of the headache. In the treatment of fever and ague, when there is an intermission, the remedy is administered upon altogether a different principle.

The administration of the quinine in this case, *i. e.*, fever and ague, should be preceded by a cathartic. It will facilitate its absorption. What is it that embarrasses absorption of quinine in these cases? It is gastric, supervening upon portal congestion, thus hindering the absorption. Quinine, morphine, and all the vegetable alkaloids, if they remain for much length of time in the alimentary canal, and are subjected to the action of the ordinary chemical fluids there, become so changed as to lose largely their special properties. These remedies, therefore, should be given upon an empty stomach. It is not unfrequently the case, as is well known, that quinine, on account of disturbance in the stomach, is not absorbed, even if it be retained. In such cases resort may be had to the hypodermic use of the drug. This man will be directed to take *twenty* grains of quinine each day for four days, then to omit two, on the fourth day to renew it again, and to report at the end of one week.

#### METHOD OF DIMINISHING THE DOSE OF QUININE.

Is there any means by which the effective dose of quinine can be diminished?

Capsicum combined with quinine will diminish the size of the dose requisite, and the same may be said of ginger and other aromatics. A good dose of cap-

sicum combined with twenty grains of quinine will act as well as thirty grains of quinine without the capsicum. Spices in general stimulate the portal circulation, and promote the flow of bile, and hence their universal use in hot climates. There is a tendency on the part of quinine and capsicum to purge, and sometimes to purge violently. In such cases the purgative action is caused by the increased flow of bile produced by the capsicum. Ginger and quinine, when combined, do not purge, and it makes a very good combination. If the medicine is administered in form of pills, capsicum may be preferable, because of the less bulk required; but, if desirable, the ginger may be given separately, and with the same effect as when combined with the quinine. The proportions should be one grain of capsicum to three of quinine; with ginger, one grain of each.

There is constant failure in the treatment of malarial poisoning by the use of quinine, and nearly always it arises from the manner in which the remedy is administered. The point to be obtained is the quick absorption of the quinine. Suppose, for example, you are called upon to prescribe in a case of malarial poisoning in which there is almost continuous vomiting, as in bilious fever. If there is gastritis present, there will be tenderness upon pressure at the pit of the stomach and in the region of the gall-bladder; there is apt to be some swelling of the epigastrium, and the patient vomits as soon as anything is taken. It is useless to administer quinine by the mouth under such circumstances, because the excessive irritation which it produces upon an inflamed mucous membrane causes its rejection at once. If injected into the rectum under the same circumstances, it will not succeed any better, because rectal absorption is diminished on account of portal obstruction.

Now, if you will apply two or three leeches at the epigastrium, the vomiting will be arrested almost certainly, and you will be able to get the quinine absorbed. Do not use either mustard or blisters here to arrest the vomiting, for they are vascular stimulants. Topical blood-letting, on the other hand, is a prompt vascular sedative.

## Progress of Medical Science.

EXCRETION OF INDICAN AND LIME IN DISEASE.—Prof. Senator, of Berlin, has discovered a very easy and rapid method of examining the urine for indican, which he now employs constantly in place of the troublesome and slow method of Jaffe. A fixed quantity of the urine to be examined is taken, and on the addition of an equal quantity of fuming muriatic acid, a dark blue cloud is frequently produced at once. This becomes more distinct in the careful addition guttatim of a saturated solution of the chloride of lime. The operator must be careful not to add an excess of the lime, as the cloud would thereby be decolorized. The indigo which is developed from the indican by this procedure may be extracted by means of ether, turpentine, or best of all, by chloroform, which combines with the indigo rapidly and completely, and falls with it to the bottom of the glass. The quantity of indigo present can be roughly estimated from the coloration of the chloroform. The method takes no more time than, and is at least as exact as the usual method of examination for albumen.

Prof. Senator does not agree with Jaffe in ascribing the increase of indican in the urine to the decomposition of food in the intestine, since the increase is greatest in cases in which the intestine contains little or no food. In peritonitis and ileus, it is true, large quantities of indican are found in the urine, but in these diseases very little food is taken, and most of what is ingested is vomited again almost unchanged. In the later stages of these affections moreover, the vomited matters consist mainly of greenish mucus, and after death little or no food is found in the intestinal canal. Prof. Senator found the excretion of indican in the urine enormously increased in cases of cavernoma ventriculi, although very little food was taken into the stomach. He also found it increased in cases of other malignant abdominal tumors, and of ulcer ventriculi, in acute febrile diseases, in pulmonary consumption, and in pernicious anemia and leukemia. Finally he has met with a similar increase in four or five cases of *idiopathic atrophy of the kidney* which was not accompanied by any disturbances of digestion. The combination of increased excretions of lime and indican has already been noticed in these columns (No. 352).—*Berliner klin. Wochenschr.*, Oct. 1, 1877.

**METALLOTHERAPY AT THE SALPÉTRIÈRE.**—M. Burg has based a system of therapeutics on the now universally admitted fact, that the application to the skin of certain metals, such as gold, zinc, and copper, in the form of bracelets, will cause the return of sensibility in cases of hysterical anesthesia. To ascertain how far this system is tenable, M. Chareot has administered internally to five patients at the Salpêtrière, the same metals that were found to be active when applied externally. The first patient had presented the most varied forms of hysteria for eleven years, and at the time the metallic treatment was begun, was suffering from complete left hemi-anesthesia. The application of the gold bracelets produced a return of sensibility. On June 11th the internal treatment was begun with one-third grain of the chloride of the oxide of gold and sodium. In twelve days the sensibility was normal, and at the end of a month the patient had gained thirteen pounds in weight. The recovery has been apparently complete. In the second case the recovery was equally rapid and complete. The third case was one of hystero-epilepsy; the hysteria was cured, but the epilepsy persisted. The fourth patient was also suffering from hystero-epilepsy. She was sensible to copper, and for a time improved rapidly under the use of copper bracelets. She finally became insensible to the external application of the metal, and was then placed on the internal use of the hydrated binocide of copper, and the waters of Saint-Christan. Of the former, at first two-fifths and afterwards four-fifths of a grain were given at a dose. After a time it was replaced by the albuminate of copper, the dose of which was gradually increased to one and one-half grains per diem. The improvement was satisfactory until the patient refused to take the medicine. The fifth and last case had also begun to improve, when she refused to take the medicine. One case of obstinate hysteria in M. Hardy's service proved entirely refractory to the metallic treatment both external and internal.—*Gazette des Hôpitaux*, Sept. 29, 1877.

**ACTION OF THE SULPHATE OF QUININE ON THE FŒTUS AND THE NEW-BORN CHILD.**—In a paper published in the *Annales de Gynécologie* M. Burdel maintains that when a pregnant woman, no matter what be the term of the pregnancy, is attacked with intermittent fever, she is liable to abort seven times out of ten, unless she is treated with quinine. It is very

generally believed that this drug will itself cause abortion, but M. Burdel reports several cases which demonstrate that enormous doses of it can be taken without injury to the embryo, and without shortening the course of the pregnancy. He denies that malarial fever can be transmitted to the fetus in utero, or to the nursing infant through the milk of the nurse. He has never known infants to suffer from fever or other malarial symptoms before the fourth month. He has, on the contrary, frequently observed young infants fed entirely on the mother's milk to remain fresh and rosy, although the mothers themselves were devoured by fever and reduced to a state of profound anemia. This immunity, however, does not persist after the process of dentition begins.

M. Burdel has devoted an important portion of his paper to the study of the action on the new-born child of the milk of a woman who is taking sulphate of quinine. Nothing is more variable and inconstant than the transmission of medicines, and of quinine in particular, by means of lactation. He has known children to be fatally poisoned by the milk of women who had been brought under the influence of this drug. He has deduced from his observations a certain number of facts, on which rules for the administration of quinine may be based. Thus he found that the drug was absorbed more rapidly, and was contained in larger quantities in the milk when it was given on an empty stomach; on the contrary, when administered with the food, it appeared in the milk less rapidly and in smaller quantities, and was consequently less toxic. As the infants advance in age they become less susceptible to the influence of the quinine in the milk, and after they attain the age of five or six months cases of poisoning rarely occur. When it becomes necessary to administer quinine soon after delivery, its injurious effects on the child may be prevented by giving it with the meals or with some food, and by emptying the mother's breast artificially three hours after its administration. When these precautions are observed, M. Burdel claims that the infant may be allowed without fear to nurse the mother during the entire time that she is taking the quinine.—*Journ. de Méd. et de Chir.*, October, 1877.

**SUPRAPERIOSTEAL ABSCESS.**—A paper with this title, by Dr. Duplay, was read in the Surgical Section of the *International Congress of Geneva*. The only form of periosteal abscess that has hitherto attracted much attention is the subperiosteal, but Mr. Duplay places alongside of it another variety, to which he has given the name suprapariosteal. It is a collection of purulent matter close to the bone, formed at the expense of the external layers of the periosteum and the neighboring cellular tissues. The bone is not denuded. These suprapariosteal purulent collections are due to various causes, the most frequent being bad hygienic conditions and serofula. The affection may be acute or chronic. The acute form may be distinguished from the subperiosteal abscess, by the facts that its borders are less sharply defined and the general symptoms are less severe. The chronic form may be distinguished from chronic periostitis by the absence of thickening of the bone around the focus of disease. After the abscess is opened, cicatrization takes place slowly.—*Lyon Medical*, October 7, 1877.

**THE CATHOLIC UNIVERSITY OF PARIS.**—The Archbishop of Paris recently presented to the Minister of Public Instruction, on the part of the Catholic University of Paris, a petition praying for the recognition of the university as an establishment of public utility.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, November 17, 1877.

## THE LESSON OF A BOARD OF HEALTH PAMPHLET.

A BRIEF, but very explicit and practical report upon defective plumbing and house-drainage in this city, prepared by Sanitary Inspectors C. P. Russell, M.D., W. H. B. Post, M.D., and T. J. Nealis, Sanitary Engineer, and illustrated with simple diagrams as to the best methods of constructing and arranging traps, waste-pipes, soil-pipes, and sewer-pipes, has just been published by the Board of Health, after careful examination and approval by the Sanitary Committee. While the pamphlet enters into no discussion of the larger aspects of the subject, one of the most important in the department of public medicine, it condenses the leading principles of sanitary engineering and plumbing into a few simple rules which should be placed in the hands of every plumber in this city, by way of convincing the members of that obstinately ignorant fraternity that it really is not an essential necessity of their business to hold themselves responsible for twenty-five per cent. of the deaths that occur from zymotic diseases, the larger mal-engineering that controls the general administration of the sewerage system being responsible for most of the seventy-five per cent. remainder.

The general subject of inefficient house-drainage and sewer-gas poisoning has, of late, given scope and direction to some of the most brilliant and exact scientific investigations in this country as well as in England, where a literature of the sewage question at once theoretically brilliant and practically valuable and exact, has been developed within the last ten years. While the germ theory of diseases has not, perhaps, been established by these investigations, and while the special manner in which defective drainage and sewerage systems in cities and towns eventuates in such diseases as enteric, typho-malarial, intermittent, and cerebro-spinal fever, in diphtheria, scarla-

tina, cerebro-spinal meningitis, etc., etc., has not been conclusively made out, the fact that they are constant factors in the causation of such diseases has been demonstrated beyond a doubt. So that, whatever may be our view as to the part played by bacteria, micrococci, and other minute forms of life in diseases of the zymotic type, the practical point that defective drainage and sewerage are directly concerned in their generation has been placed beyond controversy. Dr. Pinkham's valuable notes on the causation of the recent diphtheria epidemic in Lynn, Mass.; Dr. Gerish's penetrating review of the sanitary condition of Portland; and the recent work of the Connecticut Medical Association as to the causation of the almost epidemic intermittent of late years in several counties of that State, furnish brilliant recent examples of the efficiency of the statistical method in working out the apparently inexplicable problems of public medicine, and add so many pamphlets more to the direct evidence of a constant relation between defective drainage and sewerage and zymotic and diarrhoeal disorders. It is not now denied in any quarter (except, possibly, by Dr. Dunsmore, of Vermont) that the emanations of drains and sewers, if permitted to penetrate into dwelling-houses, are not only detrimental to the general health of inmates, but liable and likely to eventuate in certain specific diseases. But, although our people are now generally aware of the peril and of its specific nature, there is, as the report under consideration very justly observes, a truly remarkable ignorance, even among the most intelligent classes of the community, including the medical profession itself, of the manner in which these poisonous gases effect their insidious entrance, and of the methods available for their exclusion. This is, in a measure, pardonable; our literature of sanitary science being of comparatively recent origin, its data scattered and inaccessible to the average practitioner, and its conclusions local, fragmentary, and often conflicting. For almost the only large and comprehensive investigation as to the contamination of well-water and its relation to local outbreaks of typhoid fever, for instance, the physician must consult the voluminous reports of the State Board of Health, Mass., as well as for a thorough study of the contamination of rivers and the relation of such contamination to zymotic diseases in the manufacturing centres dotting their margins. On the other hand, when thoroughly examined, the reports of the New York Board of Health furnish the most valuable statistical data as to the agency of defective drainage and sewerage in the production of epidemics; although these data must be collected from scattered statistical tables, the bearings of which are not always sufficiently indicated, and the value of which to the practitioner is therefore materially impaired.

The epidemic of cerebro-spinal meningitis that commenced in January, 1872, presents an illustration in point. During the first three or four months of its

prevalence the epidemic was almost entirely limited to the margins of the original watercourses of the city, and to districts resting upon water-saturated soil. Subsequently it developed itself throughout the more thickly populated sections, in constant association with overcrowding, faulty ventilation, and defective house-drainage. Isolated cases occurred in localities where these conditions did not presumably exist; but careful investigation was uniformly successful in disclosing unsuspected defects in the last particular, and thus the apparent exceptions furnished striking verifications of the agency of defective sewerage in the causation of the epidemic.

In a similar manner the scarlatina epidemic of 1870 was restricted to a well-defined territory occupying a narrow valley between One Hundred and Second and One Hundred and Tenth Streets, and extending for about a square east of the Old Bloomingdale Road—a depression but thinly inhabited, and the very symbol of defective drainage. Formerly it had been drained by several sluggish watercourses, converging from various quarters, and uniting into a single current that crossed the road by a culvert, wound lazily along a little valley, and joined the Hudson at Stryker's Bay. The culvert being an insufficient outlet during heavy rains, the valley behind it was frequently saturated, dwellings were inundated, privies invaded, and an epidemic of scarlatina punished the city for the stupidity of an engineer.

A third instance in point occurs in the epidemic of relapsing fever which forms the most important sanitary event of the report for 1870, and was traced to a dilapidated rookery in Mulberry street, occupied by three families who carried on a business of letting lodgings to vagrants of the lowest class. Cases were also identified in contiguous lodging-houses in Baxter street a month later, and thus from several centres the fever radiated. There were good grounds for believing that the original centre of the disease was one of the lowest and dampest cellar lodgings in Baxter street, the squalid tenements of which lie along an original depression extending from the Five Points to the river, the soil of which is constantly saturated with water holding in solution the surface filth of a thoroughfare of vagrancy.

Taking up the group of zymotic diseases member by member, in this manner, and comparing their statistics and centres of activity year by year with the actual state of the drainage and sewerage system, the inference is evident that the absorption of sewage matter or of sewage emanations plays the leading part in inducing outbreaks. In the rural districts contaminated well-water figures prominently in the generation of typhoid, and by English observations the fact that the seeds of the fever may be transported for leagues by railway, and distributed by milkmen, by means of milk adulterated with such contaminated water, has been established. Indeed, the investiga-

tions of a commission of English microscopists appointed for that purpose, have pretty conclusively evinced that the agent of propagation in enteric fever is the germ of a minute vegetation, discovered by a German microscopist as usually existing in well and river water contaminated with sewage. It is a familiar fact of medical science that the severest outbreaks of typhoid in the rural districts in this country, occur during periods of drought, when the wells are, as a rule, at their lowest, and it has been pointed out by Pettenkofer that in German cities and towns a direct relation exists between the subsidence of the wells to their lowest standard of water-supply and the local prevalence of the fever. Curious as the fact may appear, however, as a verity of medical statistics, the latest conclusions of German medical literature, as represented by the *Deutsche Medicinische Wochenschrift*, of Berlin, furnish undoubted evidence that the larger view of a constant relation between defective drainage and the fever is the true one. Before sewers were introduced in Hamburg, for instance, the seven years (1838-44) had a mean mortality from typhoid, as compared with the whole number of deaths, of 48.4 per 1000. During the nine years while their introduction was in progress (1845-53) the rate fell to 39.3; during the first eight years after their completion, to 29.3; during the second eight, to 25.7. For the three years 1872-73-74, the mortality from this cause was only 2.68 for the districts in which the sewerage system was perfect, 3.2 in a certain quarter where sewers were in progress, and 4.6 in the suburbs where no sewers existed. In two of these outlying and airy villages the mortality from the fever was 7.0 and 6.6 against 2.68 in the thickly populated central portions. In Halle, from 1852 to 1861, the typhal mortality was 36 per 1000, and rose during the epidemic of 1862-63-64-65 to 194, 215, 254, 166. The introduction of a new water supply in 1870 brought it down to 14. The conclusion of the writer, one of the most celebrated medical authors in Germany, after reviewing masses of data, of which the preceding are only average specimens, is that the contamination of drinking-water by sewage soaking into the earth is the special cause of the disease in German cities and towns. A series of conclusions, merely expansive of the main point established by German statistics, was arrived at in the discussion of the subject by the recent International Medical Congress at Geneva; but nowhere, perhaps, are to be found such abundant illustrations of the fact that local defects in drainage and sewerage become local centres of typhoid, typho-malarial, relapsing, scarlet, or other zymotic fever, or of cerebro-spinal meningitis and diphtheria, as are furnished by a patient analysis of the statistics of our Board of Health, with the necessary topographical maps and the data as to defective drainage and sewerage in different quarters of the city at hand, to give point and perspicuity to the dry columns of cases, street, and number.

Unfortunately, public sentiment is not yet prepared to sustain the radical correction of defects in our drainage and sewerage systems, which modern sanitary science suggests; and the Board of Health is compelled to make the best of deficiencies which should have been provided against by competent sanitary engineering while the laying out of the city was in progress. The little pamphlet issued by the Board, therefore, very properly avoids radical questions, and is content with suggesting and emphasizing the two important points of adequate ventilation and adequate trapping. The first is most readily effected by a ventilating shaft tapping the waste and soil pipes and opening upon the roof, or a few feet above it, in such a manner that a free passage of the upper air through the whole net-work of pipes is substantially secured. The Sanitary Inspectors also recommend a rear roof leader emptying into the sewer-pipe. The vicious practice of trapping at the junction of the waste and soil with the sewer-pipes prevents the free passage of air through the former. On the other hand, the house-sewer should be effectually trapped at a point between the entrance of the waste or soil-pipe into it and its junction with the street sewer—a method at once simple and effective.

It would be premature at present to discuss the bearing of sewage utilization upon public health, although the data for arriving at valuable conclusions are abundant, and the question must become one of the practical issues of applied science within the next few years.

#### THE STUDENTS AND THE LIBERAL CLUB.

The students of the College of Physicians and Surgeons of this city have been greatly exercised regarding the arrest of two of their number for ostensibly disturbing a public meeting of the Liberal Club, held in the college building. It appears that a member of the club in question, in a paper on "medical intolerance," severely criticised the action of the faculty in regard to certain matters connected with college government, and thereby aroused the ire of the students. At a subsequent meeting of the club, on the occasion of the reading of a paper by another member, also a physician, some equally obnoxious remarks were made. Several students, who were present, manifested their disapproval of the sentiments by hisses. This was the commencement of a disturbance, which, in consequence of a deliberate insult offered to the students by one of the members of the club, culminated in an uproar. The meeting broke up in confusion with the arrest of two of the supposed ringleaders. After spending a night in jail, and beguiling the small hours by "quizzing on anatomy" and singing hymns, they were brought before the magistrate, and, in the absence of any definite charges against them, were duly liberated. These, we believe, are the facts of the case, and now for the comment. While we admire the enthusiasm

of these young gentlemen in defending the cause of medicine, and in upholding the decisions of their faculty, we do not think that the end justified the means. There was no real necessity for noticing the obnoxious tirades against medicine in general or themselves in particular. In being tempted to do so by the remarks of the ex-clergyman they have committed an error of judgment, which in their cooler moments they will see better than at present. His allusion to them as candidates for wholesale murder was the merest twaddle of ignorant assurance, and was beneath their contempt. We make every allowance for the hot blood of enthusiastic youth, but this cannot excuse them from disturbing a public meeting. The hall was hired by the so-called "liberals," and for the time being belonged to them. It would have been much better for the students either to have remained silent or to have left the room, as even in such a gathering their presence was only conditional with what by the meeting might be considered good behavior. They placed themselves in the power of the club, which gladly seized the opportunity for public martyrdom. The faculty has taken the responsibility of hiring the hall to these obnoxious persons, and it is compelled to secure them peaceable possession. It can do nothing now, save learn a lesson as to its course in future—not to rent the college building for any other purposes than those for which it was originally intended. As regards the students, we hope that the milder counsels will prevail, that no more uproarious behavior will be tolerated, and that any redress for insults offered or wrongs inflicted will be sought in the proper legal manner. As an initiative, the prosecution of those parties causing the arrest on a charge of false imprisonment is eminently proper, and well calculated to settle all doubtful points.

#### Reviews and Notices of Books.

LECTURES ON PRACTICAL SURGERY. By H. H. TOLLAND, M.D., Professor of Principles and Practice of Surgery, etc., Medical Department University of California. Philadelphia: Lindsay & Blakiston. 1877. 8vo, pp. 508.

As its title indicates, this book comprises a course of lectures on surgery. The author, on account of want of time to write a book, an excuse which ordinarily is a very poor one, but in this instance is acceptable, concluded to "talk a book." In other words, the volume is made up of phonographically reported lectures on the principles of surgery, with numerous illustrations from the lecturer's experience. Although the course is far from being complete, it extends over a wide range of subjects, and is full of practical suggestions to the students. The author understands how to bring out the salient points of a subject, and well deserves his reputation as a successful teacher. To those who have attended his lectures, this work will be a valuable and interesting souvenir. Some of the cases reported are worthy of a more permanent and

available record. As it is not intended as a complete text-book for the student, all we can say of it is that it abundantly answers the purpose of its publication, and will be well received by the author's students and friends.

**THE PRACTITIONER'S REFERENCE BOOK.** Adapted to the Use of the Physician, the Pharmacist, and the Student. By RICHARD J. DUNGLISON, M.D. Philadelphia: Lindsay & Blakiston. 1877. 8vo, pp. 335.

It is difficult to define the scope of this work. Perhaps the best idea which can be conveyed of its character is, that it is a curious collection of almost all sorts of odds and ends. It may be safe to say that in no single work has so much of the kind of information, which is generally called practical, been collected before. If the practitioner or student fails to find any out-of-the-way information, he has an even chance of stumbling across it in Dr. Dunglison's reference book. Under the heading general information for the practitioner, the subject of weights and measures is exhaustively discussed in all its different relations to the metrical system. Then follow remarks on solubility of medicines in water, alcohol, ether, and glycerine, abbreviations in common use, and comparison of thermometric scales. The therapeutical and practical hints embrace some very practical directions regarding examination of patients, doses for internal administration, injection, baths, etc., incompatibles, selected prescriptions, rules for the management of children, obstetric memoranda, examination of urinary deposits, classification and treatment of poisons, how to restore breathing by Hall's and Silvester's methods, the principles of disinfection, dietetic rules and precepts, and very appropriately at the last, detailed directions are given how to conduct a post-mortem examination.

The amount of varied and exact information required in writing such a book is such that few who had not the extensive reading and wide culture of the author, would undertake the task.

**MEDICAL AND SURGICAL REPORTS OF THE BOSTON CITY HOSPITAL.** Second Series. Edited by DAVID W. CHEEVER, M.D., and F. W. DRAPER, M.D. Boston: 1877. 8vo, pp. 316.

The present volume includes the experience of the second five years of the existence of the Boston City Hospital, and is filled with interesting accounts of the medical and surgical cases. The volume opens with a description of the hospital, as it enlarged and improved within the period embraced in the history; then follow papers on medical and surgical subjects by the members of the staff. To give some idea of the scheme of the work it will be necessary merely to give the title of the various articles which compose the present volume. I. The Treatment of Epyemia by Permanent Openings, with Cases, by John G. Blake, M.D. II. On Certain Diseases of the Nervous Centres, by Robert T. Edes, M.D. III. Compound Fractures, by Geo. W. Gay, M.D. IV. Albuminuric Retinitis, by O. F. Wadsworth, M.D. V. Case of Large Renal Calculi, by C. Ellery Stedman (with lithographs by W. P. Bolles, M.D.). VI. Disease of the Brain in its Relation to Inflammations of the Ear, by J. Orne Green, M.D. VII. Notes of Cases of Pleurisy and Paracentesis Thoracis, by Hall Curtis, M.D. VIII. On Excision of the Elbow-Joint, by David W. Cheever, M.D. IX. Clinical Notes on Erythema, by Howard F. Damon, M.D. X. Sclerosis of the Spinal Cord, by S. G. Weber, M.D. XI. Cold-Water Treatment of Typhoid Fever, by Robert T. Edes, M.D. XII. Surgical Abstract (of Interesting Cases), by David W. Cheever, M.D. XIII.

Cases with Autopsies, by W. P. Bolles, M.D. (Pathologist). XIV. Significance of Pus in Ovarian Fluids, by James R. Chadwick, M.D., and lastly, tabulated Statistics of Major Operations, by B. F. Gorman, House Surgeon. We should be most happy did time and space permit to review this remarkably interesting volume in detail; suffice it to say, however, that every progressive student, and especially every hospital practitioner, cannot fail to be edified by its perusal. We have enjoyed it from beginning to end, and cannot say too much in praise, either of the manner in which the subjects have been treated by the different authors, or of the subjects themselves, each and all of which are of rare value to the practitioner as embodying the experience of able and progressive men connected with one of the first hospitals of the country. Not having seen the first volume of this series, we are unfortunately unable to make any comparison between the two; but if it is equal in interest and value to the one before us, it is an invaluable addition to a working library.

It is elegantly printed, and well illustrated with steel engravings, chromo-lithographs, woodcuts, and lithographs.

## Reports of Societies.

### MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Special Meeting, Nov. 5, 1877.*

DR. JOHN C. PETERS, PRESIDENT, IN THE CHAIR.

"IS THE HUMAN EYE CHANGING ITS FORM AND BECOMING NEAR SIGHTED UNDER THE INFLUENCE OF MODERN EDUCATION?"

DR. E. G. LORING read an exceedingly interesting and valuable paper upon the above subject, and began by stating that all eyes, so far as their optical condition was concerned, might be divided into three classes, the normal, the far-sighted, and the near-sighted. A near-sighted eye was one the length of which was too great, so that the question might be put, "is the human eye, under the influence of intellectual pursuits, gradually increasing in length?" A direct answer to that question was contained in Ribot's late work on heredity, in which it was affirmed "that since constant study creates myopia, and hereditary influence most frequently perpetuates it, the number of short-sighted persons must necessarily increase in a nation devoted to intellectual pursuits."

This was the opinion of the majority of those who had paid most attention to the subject, and it became a matter of great importance to investigate carefully the evidence upon which that belief was based. It rested principally on two factors: *First*, the influence of heredity, and, *secondly*, on that of close application of the eyes. In regard to heredity there was little or no statistical evidence of any scientific value, but such as did exist certainly did not show a marked hereditary tendency. Thus the statistics gathered by Dr. Loring, from over 600 persons, showed that only about six per cent. had either father or mother myopic, and that was corroborated by what had been found by Cohn and Emmert. What might be termed legendary testimony had been handed down from the remotest time, and the conviction that myopia was hereditary had been firmly fixed in minds of all people from the remotest past, and traditional evidence of such a character was apt to be virtually if not cate-

gorically true. The influence attributed to heredity had been, in the mind of the reader of the paper, exaggerated probably from a want of attention to that secondary law of heredity known as the law—or, rather, since the principles on which it acted were almost unknown—the *fact* of reversion, through which an organ, after having been modified, returned to its original condition in a future generation. One of the principal factors which influenced this return to the normal condition would, in the author's opinion, be the state or degree of perfection of the organ for the performance of its function. The normal standard as it now existed could be demonstrated mathematically to possess the widest range of vision with the least effort to the beholder, and as this condition would be more advantageous for man in a savage state than in a civilized condition, it would in all probability be developed early and long maintained. Consequently no change would be apt to take place in its form unless a great change had also taken place in the nature of the "conditions of its existence"—a change which should be brought to bear, not on a few individuals, but on the community at large; and not on one sex alone, but upon both sexes alike. In the author's opinion we need go no further to look for such a change than in modern devotion to literary pursuits, and especially to that phase of it denominated compulsory education—a force of great power, of modern origin, and rapidly extending development. This brought the author to the consideration of the second factor in the production of near-sightedness—the prolonged use of the eyes.

Over fifty years ago Ware, the famous English oculist, pointed out the fact that myopia was more frequent in the cities than in the country, where the application of the eyes was less, the objects greater and at greater distances, and that the amount of myopia increased with the amount of study and within certain limits with the age of the student. These observations had been corroborated by the elaborate investigations of Cohn, in Germany, and by many observers in other countries. As an example of the manner in which the investigations were made, Dr. Loring referred to some tabulated charts, in which the increase of myopia was shown by curves, expressing in per cent. the gradual increase of near-sightedness from the younger to the older years of school life. The charts represented the results of an examination made by himself and Dr. R. H. Derby, of this city, upon the eyes of 2,265 pupils in the public schools of New York, over 4,000 in Russia, and over 3,000 in Germany. In the American diagram the myopia rose from less than 4% at 6 years to 26% at 21 years; while in Russia it rose from 11% to 44%, and in Germany from 10 to the enormous amount of 63%. In all the statistics ever made the same increase, vary as it did in degree in the different countries, was invariably noticed. The statistics made by himself and Dr. Derby did not vary materially from those made previously by Drs. Prout and Mathewson, of Brooklyn, Dr. Cheatham, Dr. William Ayres, Dr. Callan, and others. Most of those statistics were compiled by Dr. Webster, and afterwards published by Dr. Agnew.

From such statistics alone it had been assumed by many that the increase in near sightedness was directly proportionate to the amount of work, but it was to be remembered that, as near sightedness might, and often did, result independently of study, the later years of life would always show a greater percentage of myopia, produced oftentimes by other causes. It was necessary to show that myopia was more frequent among those who studied more than among those

who studied less at the same age. Ware and Cohn had done this, the latter showing that while the scholars in country schools showed less than 2%, those in cities of the same ages showed 10%. Erismann showed that of those scholars who studied two hours out of school, 17% were myopic; of those who studied four hours, 29%; and of those who studied six, 40%.

It had been shown by undoubted evidence that near-sightedness was greater in Germany than in any other cultivated nation. Donders had declared that in no other nation in Europe had he found it so prevalent in every rank of life as in Germany, and the same was true of those of German parentage in this country. Thus Dr. Loring found that of the scholars of German parentage there were 24% near-sighted. Of the American, 19%, and of the Irish only 14%. It did not follow, however, that German near-sightedness was due to over-study alone, for there were many other factors in force among them which did not exist, or existed to a less degree, in other nations, such as peculiarities of food, want of out-door exercise and indifference to ventilation, combined with a general sedentary life, all of which favored that laxity of tissue which found its expression in the eye in the distention of the investing membrane, which was near-sightedness.

It has been shown that the most studious nations were the most near-sighted, and it ought to follow logically that where the near-sightedness was less the cultivation and literary achievement would also be less. It was universally admitted that the English were much less near-sighted than the Germans, and less even than the Americans—and yet no other nation in the world could show such a list of brilliant names in every department of literature for the past 400 years as England. That could not have been produced without a corresponding use, often excessive, of the eyes. And it was the same in her arts and sciences. Superior to Germany in all her mechanical arts, the English mechanic was nevertheless far freer from myopia than the German. What, then, was the reason of this? It seemed to the author that it was due principally, if not solely, to the most important fact which could in this connection be brought to the attention of his hearers, and that was that myopia was a disease of childhood, being formed almost invariably in childhood, or at the most, in early adolescent life, while the tissues were elastic and yielding. The great time for its development was between the eighth and fifteenth year. After the sixteenth or eighteenth year, over-use of the eyes might produce other and graver diseases of the eye, but it would not produce near-sightedness. It was the observation of that fact, whether consciously or unconsciously, that had made England so eminently a literary nation, and yet so free from near-sightedness, while it was the violation of it, that is, the compelling of a great amount of study at a tender age, which had made Germany the shortest-sighted nation on the earth. That also explained why it was that hitherto so many mechanical callings which required long-continued tension on small objects, such as jewellers, watch-makers, engravers, draughtsmen, and type-setters did not show nearly as great a tendency toward myopia as the literary and professional occupations. Until very recently the early education of apprentices to skilled labor was neglected. They had but little school-learning, did not even approach the niceties of their calling till the sixteenth or seventeenth year, and then only very gradually. Their work was moreover often interrupted and often changed; and when they did arrive at what required close or even excessive application of the eye, the

dangerous time for the development of myopia had passed. That was very different from what obtained with the student whose closest, most confining, and arduous tasks came just at an age when he was least able to bear them.

From what had preceded a doubt had arisen in the author's mind whether the results gained in Germany in the last half century, or since her method of compulsory education (1812), had been proportionate to the tremendous expenditure of force used, and whether that reverence for, and dependence upon authority—that endless and accumulative repetition of the works of others, without which no task is ever performed, had not discouraged her originality and crippled her invention.

The conclusions arrived at were that there was an hereditary tendency to myopia, though its degree had not yet been established, and that the amount of near-sightedness was, other things being equal, proportionate to the amount of study. It was the author's opinion that if compulsory education was carried out in its original meaning and applied to every child, the amount of near-sightedness must necessarily increase, and that if Germany was going to be the type, not only the educated classes, as the term was now understood, but also the world at large, would in time become near-sighted. On the other hand, by attention to the simple law of controlling the time of life at which the use of the eyes was carried on rather than the amount, the present standard, or normal eye, formed in the remotest past may be continued indefinitely.

In finishing his paper, Dr. Loring remarked that two questions had presented themselves to his mind, while making his investigations on myopia in the public schools. One was whether the word instruction was always synonymous with education, and the second, whether, while we were reducing the number of those absolutely blind in our asylums by improved methods of operation and treatment, we were not, by over-use of the eyes at school, laying up a future evil which, though milder in form, would from its very frequency entail a greater and more lasting detriment upon the race.

The paper being before the Society for discussion,

DR. JOHN C. DALTON expressed his commendation of the opinions advanced by Dr. Loring relating to early education. He also doubted whether excessive education of young children was to be of benefit to the race at large. He was not disinclined to believe the remark once made that "some children were educated beyond their capacity." It was quite a prevalent idea that the more education a child received the more capacity it would develop in after years, but that was very questionable. Parents were pleased to see their children do better than other children in various studies, and in general the younger and more precocious the child, the more they were pleased; it often became a matter of personal vanity upon the part of parents. Athletes made the same mistake as studious men. They thought that if they could lift a 180 pound dumb-bell they were in good condition, but the fact was that development of muscle alone did not give bodily vigor. Dr. Dalton did not in any sense wish to be understood as depreciating intellectual cultivation, but he had grave doubts as to whether such cultivation was synonymous with the reading of books.

DR. H. D. NOYES remarked that he could add but little to the valuable statements made in the paper. He had never before heard it stated that it was a fact that the organs of special sense were less likely to be sub-

ject to the influence of heredity than other organs of the body.

It certainly seemed true, however, that heredity did not have a large influence in the production of myopia. He had an impression that if there was any malformation in consequence of that influence, it was in the form of hypermetropia, for that defect could be traced in families much more frequently than could myopia. That would at least be an interesting item for examination, and might yield some useful results. He thought that the concluding portion of Dr. Loring's paper, after all, contained its most essential feature. Prolongation of the eyes resulting in myopia was evidence of "laxity of tissues." The defect, in a large proportion of cases, was found in those whose general vigor was not up to the normal standard.

He fully coincided in the opinion expressed that the small percentage of myopia occurring among the English was, in a great measure, because of their great robustness in general health. The same remark, to a certain extent, might be applied to our own country. We were abundantly capable of enduring fatigue, and that was essentially the same as power of resistance in tissues. The Doctor fully concurred with the remarks made by Dr. Dalton. The question of myopia was one that was closely related to physical development. As this evil effect upon the eyes occurred so early in life, he believed it important to discourage parents from prompting children to study much out of school. Again, the print in school-books should never be such as made them unpleasant to the eyes of any who read them.

DR. CALLAN thought the system of schooling in Germany had more to do with the production of myopia than the food and habits of the people. He placed school hygiene *first*, and hereditary influence *second* as causes of near-sightedness.

DR. MITTENDORF remarked that with Dr. Derby he had examined the eyes of between two and three thousand students, and had found about the same percentage of myopia as had been reported by Dr. Loring. He did not think there was any danger of the same percentage of near-sightedness being reached in this country as existed in Germany, because of our comparatively well ventilated rooms and a better general observance of hygienic measures. He believed that it would be difficult to determine whether hypermetropia was present or not, because it was usually so slight that children were not aware that their eyes were in any way deficient.

DR. O'SULLIVAN drew attention to the fact that in all of our public schools the rooms were over-crowded with pupils, and in most instances were very poorly ventilated. In some school-rooms he had also found that the seats were so placed relative to light that the pupils could only with great effort see figures made upon the black-board.

The idea that the school-rooms in the public schools of the city of New York were well ventilated and were not overcrowded, was erroneous.

Drs. Matthewson, St. John, and McIlvaine participated in the discussion. A vote of thanks was extended to Dr. Loring for his paper, and the Society adjourned.

---

GOtha.—The authorities of the city of Gotha, in Germany, have made a grant of 72,000 marks for the erection of buildings in one of the cemeteries of the city, in which the process of cremation can be carried out.

## Obituary.

PROF. PAUL F. EVE, M.D.,  
NASHVILLE, TENN.

PROFESSOR PAUL FITZSIMMONS EVE, the distinguished Southern surgeon, died suddenly, while in attendance upon a patient, November 3d, aged seventy-one years. He was born June 26, 1806, near Augusta, Georgia; graduated at the University of Georgia in 1826; as M.D. at the University of Pennsylvania in 1828, and was a student several years in Europe. He served as a volunteer surgeon in the Polish revolution of 1831, and received therefore the Golden Cross of Honor of Poland that year. He became Professor of Surgery in the Medical College of Georgia in 1832, in the Louisville University in 1849, in the Nashville University in 1850, and in the Missouri Medical College, St. Louis, in 1868. In 1870 he accepted the chair of Operative and Clinical Surgery in the University of Nashville, which position he held at the time of his death. As a representative man for the South he was, in 1857, chosen President of the American Medical Association. During the rebellion he served as surgeon in the Confederate Army, and for the greater part of his professional career was identified, directly or indirectly, with medical journalism in his section of country. A hard worker in his profession, his strictly methodical and temperate habits enabled him to carry his burden of duties up to the very threshold of death, and lay them down to enter at once into his eternal rest. Prof. Eve, as a surgeon, will be best remembered in connection with his remarkable successes as a lithotomist. Of ninety-two bilateral operations for stone eight only terminated fatally. His last notable contribution to medical literature was his address on Surgery at the International Medical Congress in 1876.

Dr. Eve was by faith a Presbyterian, and an ardent supporter of church interests.

He was twice married. First, in 1832, to Miss Sarah Louisa Twigg, who died April 10, 1851. He married his second wife, Miss Sarah Ann Duncan, of South Carolina, January 13, 1852. She now lives to mourn his loss. He also leaves three sons and two daughters.

PROF. MARTYN PAINE, M.D.,  
NEW YORK.

PROF. MARTYN PAINE, the distinguished medical savant, died November 10th, as the result of a compound fracture of the elbow-joint, aged eighty-three years. Few medical men had greater opportunities for usefulness, which were so well improved, than the subject of our sketch.

He was born July 8th or 10th, 1794, at Williamstown, Vt. He was graduated at Harvard University in 1813, and took the degree of M.D. from the Medical Department of that institution in 1816. Thence he went to Montreal, and engaged in practice till 1822, when he removed to New York, in which city he lived during the remainder of his life.

In 1841 Dr. Paine, with four others (Drs. C. A. Lee, Alfred C. Post, G. S. Bedford, and A. Sidney Doane), established the Medical College in connection with the University of the City of New York. For many years following he filled the chair of Institutes of Medicine and Materia Medica, and subsequently that of Therapeutics and Materia Medica.

The greatest service done by Martyn Paine to science

and humanity was his procuring the repeal of the law which made it a penal offence to dissect a human body. He succeeded in convincing the representatives of the people, assembled in the Legislature of this State, that such a law was irrational and a perverse interference with the advance of knowledge of the healing art, and despite the tremendous opposition that was raised against him, a law was enacted by which any regularly incorporated medical college in the State of New York was entitled to its share of legitimate material for the better study of anatomy, physiology, and surgery. Dr. Paine was the author of numerous works, among which are "The Cholera Epidemic of New York," "Medical and Physiological Commentaries," three volumes, 1840-44; "Materia Medica and Therapeutics," 1842; "The Institutes of Medicine," 1847; "The Soul and Instinct Distinguished from Materialism," 1848, subsequently incorporated in the "Institutes." In 1852 Dr. Paine published, for private circulation, a memoir of his son, Robert Troup Paine. In 1856 he contributed an elaborate essay on "Theoretical Geology," to the *Protestant Episcopal Quarterly Review*, controverting the geological interpretations of the Mosaic narrations of creation and the flood.

He withdrew from the Medical Faculty of the University about twenty years ago, but was soon after elected Professor Emeritus of Materia Medica and Therapeutics, which position he held till the time of his death. About the same time that he gave up his active duties in the college he quit his medical practice and devoted himself to close study and writing. He was a member of a large number of learned foreign societies. He was always a strict dietitian, and for the last twenty years had subsisted on vegetable food exclusively. In his practice he went upon the plan of depleting rather than "building up" his patients as a preliminary to effecting a cure. His convictions were strong, and he was a powerful talker as well as a vigorous thinker and writer. Many of the old graduates of the University College will recollect how earnestly and sonorously he laid his precepts upon them.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from Nov. 4 to Nov. 10, 1877.*

HAMMOND, J. F., Lieutenant-Colonel and Surgeon. Granted leave of absence for six months, from Nov. 1, 1877. S. O. 227, A. G. O., November 6, 1877.

FORWOOD, W. H., Major and Surgeon. Assigned to duty as Post Surgeon at McPherson Barracks, Atlanta, Ga. S. O. 175, Department of the South, Nov. 3, 1877.

BUCHANAN, W. F., Captain and Assistant Surgeon. Assigned to duty at Chattanooga, Tenn. S. O. 176, Department of the South, Nov. 6, 1877.

KINSMAN, J. H., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon, Mt. Vernon Barracks, Ala. S. O. 163, Department of the Gulf, Nov. 4, 1877.

SPENCER, W. G., First Lieutenant and Assistant Surgeon. Leave of absence extended 15 days. S. O. 262, Division of the Atlantic, Nov. 9, 1877.

SUFELDT, R. W., First Lieutenant and Assistant Surgeon. To accompany companies of Fifth Cavalry to Fort D. A. Russell, Wyo. Ter. S. O. 126, Department of the Platte, Oct. 29, 1877.

EDWARDS, L. A., Lieutenant-Colonel and Surgeon. Died at Washington, D. C., Nov. 8, 1877.

**MEDICAL EDUCATION IN PARIS.**—The medical aspirants going to Paris fall under two general classes: First, those who want the complete French degree of M.D.; and, second, those who want only a certain limited amount of theoretical or practical instruction in the French medical class-rooms, anatomical theatres, or hospitals. It is evident that in dealing with the wants of the first class, all those of the various subdivisions of the second class will be included.

The complete course of study embraces a period of at least four years. The class-rooms are nominally free and open to any one who sits down and behaves like a gentleman—the professors being paid by the state. No certificates of attendance will, however, be given, and no diplomas, unless certain fees be paid and examinations undergone. The sum total of all the fees payable to the Paris Faculty of Medicine for their degree amounts to 1,260 francs, or about \$252, divided as follows:

Inscription fees of thirty francs each, payable at commencement of each quarter, 3d November, 3d January, 1st April, and 1st July, for four years—in all, sixteen inscriptions.....	\$96
Examination fees at the end of the first, second, and third years, thirty francs each year, and three in all.....	18
Final examination fees at end of fourth year, certificates and diploma of M.D. included.....	138
Total.....	\$252

Every student, in presenting himself to take his first *inscription*, will have to depose (1st) a certificate to prove that he is at least sixteen years of age; (2d), if a minor, the consent of his parents or guardian; (3d), a certificate of good life and morals; (4th), the diploma of Bachelor of Letters and Science, or, if a foreign student, its equivalent. In the case of an American, this equivalent would be the B.A. of any good home university, or a series of certificates from some competent authority amounting to that. It must be understood, however, that the French Faculty (or rather the Minister of Public Instruction, who is the final judge) is always ready to grant every reasonable favor to strangers, who show, by the trouble and expense they put themselves to in coming from the United States, that they are seriously bent on the acquirement of knowledge. As to students who have already acquired more or less proficiency in medicine in a university, academy, or faculty outside of France, they have the right to demand a corresponding status and a "concession of inscriptions" in Paris. The documents on which this demand may be founded should be forwarded to the Rector of the Faculty, who will submit them to the proper authorities and indicate the

result. In this way a foreign student may shorten his four years by one or two or three years, as the case may be. In case the applicant should already hold an American or English M.D., it is usual to concede to him *all* the inscriptions, and excuse him from passing the examinations of the first three years; he will only have to undergo the final examinations. In all cases of "concessions," however, whether partial or complete, the full fees of 1,260 francs have to be paid, as if the classes had been followed year by year. Lastly, foreign doctors may practise their profession in France, without taking the French degree or passing any examination, by a special authorization of the Minister of Public Instruction. To gain this, the fees will have to be paid as above, and the following documents deposited in the hands of the Rector of the Academy of the place in which they desire to practise: (1st), a recommendation from the Minister representing their nation in Paris; (2d), an indication of any special scientific or literary labors which they have accomplished, or on which they are engaged; (3d), their diplomas, accompanied, if necessary, by a certified translation of the same.

The young student, having paid his inscription fee of thirty francs in advance, is presented with a card (good for three months), which opens to him the library and all the museums and class-rooms necessary. He is also furnished with a paper of directions. The hours and places of the various lectures, hospital and other, are posted up in the hall of the School of Medicine (Rue de l'École de Médecine), and in most of the public libraries, etc., or the printed list can be obtained for a few cents by writing to "M. Craville-Morant, 20 Rue de Sorbonne," for the *Indicateur des Cours Publics*.

Students have the choice of a large number of professors; provided they pass their examinations and pay their fees, they may even get their instruction from what are called the "Free Professors"—that is to say, from those outside the faculty who compete with its members and take what may be called private pupils. Naturally these demand an extra fee. To take one of the best examples, the five months' course of anatomy given by Dr. Fort costs, subjects and lectures included, 300 francs. This style of instruction is especially suitable to foreign students who do not care to follow all the regular classes.

**A MILD CLIMATE AND MINERAL SPRINGS.**—Dr. D. B. Messenger writes: "Dear Sir—After five years' observation, I am convinced that the mild climate, pure dry air, and fine mineral springs of West Texas afford to those needing a change of climate advantages equal, if not far superior, to those found in the more eastern Gulf States with their humid atmosphere; and since the railway was completed to the city of San Antonio, many who wished to winter in a mild climate have been benefited by a sojourn in this salubrious region of country. The most noted medicinal waters are to be found at Lampasas, Luling, and Sutherland Springs; white, black, and blue sulphur chalybeate, magnesian, iron and alum, and other waters, are found at Sutherland Springs; the large bathing springs of white and black sulphur water have a temperature of 78° Fahr.; the chalybeate, 72° Fahr. Here one can select a tonic or a diuretic, an aperient, astringent, or an alterative spring water, as the case may need. These springs are thirty miles from San Antonio, on the Rio Cibolo, in the centre of a belt of oak opening 15 miles wide. Deer, turkey, geese, ducks, quail, and other game reward the sportsman while the river affords the finny tribe in abundance."

## REMARKS UPON

THE MECHANISM AND TREATMENT OF  
PULMONARY COMPLICATIONS OF  
ACUTE CARDIAC DISEASE.\*

By BEVERLEY ROBINSON, M.D.,

PHYSICIAN TO CHARITY HOSPITAL, ETC.

SCARCELY a work has appeared on diseases of the heart which does not treat at length of pulmonary lesions that so frequently complicate their chronic affections. Nor is this a surprising fact, when we consider the intimate relations, anatomical and physiological, which exist between the heart and the lungs, and are made aware how nearly connected must therefore be their divers changes of tissue. Thus it has become an established law, that if an organic disease exist for any length of time in either the cardiac or pulmonary structure, the sequel of the primitive disturbance is manifested by signs of trouble evolved in the neighboring organ previously healthy. It is regrettable, however, in those old maladies which have left indelible traces of their presence, that we are frequently at a loss to determine which is the viscus which originated the march of morbid events. At times, no doubt, it is the heart, which, becoming affected by the dyscrasic influence of rheumatism, pyæmia, or typhic forms of disease, has paved the way to congestion of lung tissue, to hypostatic pneumonia, to cheesy softening, or tuberculous development. Again, it is a probable belief that the lungs have been attacked with a form of some usual disease of inflammatory type; but instead of returning in the convalescent stage to their original integrity, have remained in a condition in which their function is evidently trammelled, and normal heart-action rendered impossible. But in numerous instances, after a long lapse of time, to be able to *affirm positively* in which system the pathological changes have first developed themselves, is most difficult. Fortunately, such obscurity is far less likely to attach itself to the invasion of acute disorders. Consequently, their début and ulterior march can be accurately and fully learned. And from this knowledge the practical services which must finally result are readily appreciable. We are thus enabled to form correct opinions with respect to the relations of these diseases to each other, and by watching closely the mechanism according to which certain ascertained consequences are affected, more rational and trustworthy therapeutical measures will sooner or later be universally employed. Some such reflections as the foregoing have made me desirous of correlating in the space of a short article a few facts which, though known to the profession, are not united in an easily assimilable form in regard to the pulmonary complications of acute disorders of the heart. Just so soon as circulation through the heart is at all embarrassed by acute organic disease of its structure, hæmaturia is immediately interfered with, and other troubles of the respiration, functional or organic in their nature, sooner or later occur. These pulmonary complications frequently become of primary importance, and, in fact, tend to the cardiac affec-

tion its imminent gravity. Besides, when once they are developed, unless speedily and thoroughly cured, they tend constantly to aggravate the heart-lesion and to lessen the time during which the patient may hope to live in comparative comfort. By attention and care in regard to their period of attack, their further development may sometimes be checked, or indeed completely aborted. If allowed to run their course unrestrained, they lead in many instances to a rapid and fatal termination, and in themselves are frequently to be considered the proximate and efficient factor in causing it.

As we shall note further on, these accidents differ materially in their nature and gravity. Sometimes they are purely functional, again they are organic. In the first case they are painful and distressing, but not as a rule dangerous. In the second case, they are undoubtedly dangerous, and are therefore to be met immediately with the use of active opposing agents. But the amount of danger will depend to a great extent upon whether or not the pulmonary complication be inflammatory, or merely congestive in type; whether or not the last-mentioned condition be permitted to transform itself into the more severe form of disease. Let us now study in particular those lung complications which follow closely upon pathological processes acutely developed in the endocardium, the pericardium, and the muscular heart structure itself. Take for example, and as a first thought, the invasion and ordinary march of endocarditis. What do we see? Dominated by rheumatic dyscrasia in manifold instances, we have a localized inflammatory process attacking the endocardial membrane. The heart's action is accelerated and increased in force. The number of pulsations and respirations are both more rapid. The patient is usually a sufferer from moderate dyspnoea, and will at times indicate the precordial region as the seat of sensations of oppression, if not of absolute pain. Upon auscultation we are able to discover a cardiac murmur more or less loud, and of varying tone, especially distinct over the orifice most affected. The physical condition of this orifice, in those somewhat rare cases where it has been examined shortly after the period of invasion, is as follows: the *pourtour* of the valve at its adherent margin is thickened and red, velvety and roughened in aspect, and may present small deposits of fibrine upon its surface. But beyond the outward appearance, there is also the dynamic or vital influence which should be estimated. The valve itself contracts badly, passes with difficulty from the state of dilatation to the state of tension, and is at times, as it were, "convulsed." In this way, doubtless, the stage of endocarditis, in which even the normal heart-sounds are deadened and which precedes that of abnormal bruits, may be explained.\*

At a later period of the physical condition described we have added to it a certain amount of rigidity and narrowness of the orifice. Against this fresh obstruction the heart reacts with greater energy, and according to Savart's law we must have a bruit of which the intensity is in direct proportion with the rapidity of the blood-flow. So long as the vital trouble on the one hand, the mechanical obstruction in the heart on the other, do not *notably* interfere with the circulation, respiration is but slightly affected and dyspnoea is moderate, or entirely absent. If, on the contrary, the one or other be specially accentuated, the result is, immediate and more considerable trammelling of the respiratory function takes place. After this manner

\* Read before the New York Academy of Medicine, September 20, 1877.

\* Monneret, Pathologie Interne, vol. i., p. 225.

we can explain the apparent discrepancies which classical authors afford.

If dyspnoea is evident, there will usually be present a concomitant condition of passive hyperæmia of the bronchial mucous membrane, for endocarditis in the adult almost always affects the left side of the heart, and must of necessity produce an excess of tension in the pulmonary circulation, so soon as acute obstruction or insufficiency is produced at either valvular orifice. More certainly, however, would this result if the pathological lesions affect the mitral valve. Such congestion is usually recognized during life by dullness on percussion and disseminated bronchial râles. But these physical signs are occasionally absent, and the dyspnoea seems to be related to an influence of nervous origin.\* Not infrequently, also, a most distressing form of obstructed breathing is due to coagula, formed in the right side of the heart.

The patient's breast heaves in an exaggerated manner, the respiration is noisy and laborious, and the general aspect of the body is pale, while the cheeks and extremities are cyanosed. There is, indeed, evidence of a violent, agonizing struggle for air against rapid asphyxia. If the lungs be percussed at this stage, we are surprised to produce an elevated tone, such as one observes in excessive vesicular emphysema. There are no râles present, and no other signs of pulmonary congestion. What is the explanation of this condition? On the one hand, the heart has been making its best effort to send a sufficient amount of blood to the lungs, but without adequate result. Little by little the supply diminishes. The deposit of fibrine within the ventricles of the heart augments, the lungs become nearly bloodless, and the cardiac contractions exhausted. On the other hand, we have a constant influx of atmospheric air into the lungs with each inspiratory effort, and the pulmonary vesicles are distended to their extremest limit. Of course hæmatisis cannot be continued in a sufficient measure, and excessive dyspnoea is the immediate necessary result. This painful condition was first insisted upon by Lavirotte † many years ago. It has since been reaffirmed by myself. ‡ If, instead of affecting the right ventricle, these fibrinous coagula be formed in the left heart, we have also a distinct order of phenomena produced, viz.: the pulmonary circulation is rendered much tenser from backward pressure, and pulmonary congestion and œdema are the rule. Blood is found in excessive quantity in the pulmonary structure, while the contrary holds true of air. Hæmatisis is likewise much obstructed, and dyspnoea is intense, but the mechanism of their production is different from that of the first-named condition. In that form of endocarditis known as "diphtheritic" or "ulcerative," capillary emboli or their consequences are usually found. The consequences are hæmorrhagic infarcti and purulent formations in different viscera.

Singular to say, these effects are not so frequent in the lungs as in other organs. In illustration of this fact I would refer to a case lately presented by me to the New York Pathological Society, § where infarcti were formed in the kidneys, spleen, intestine, etc., but none in the lungs. As an explanation, it has been said that ulcerative endocarditis, like the ordinary form of this disease, affects as a rule the left side of the heart, and the pulmonary circulation is therefore out of the sphere of such accidents. This is not wholly correct, for though the first half of the statement is

true in the case of adults, we know that branches of the bronchial artery *may* become plugged, and occasion local death of tissue. Rather than admit the fact, whenever pulmonary infarcti were discovered with a morbid condition present of the left heart, and though they were clearly due to capillary embolisms, affirmation was made that the lesions of the lung were of more recent date than those of other viscera, and were therefore secondary to, or consequent upon, similar lesions formed elsewhere. While in some instances this is a fair statement, it is not so in all; for several examples have already been published where microscopic examination could justify no such explanation (Duguet and Hayem). Moreover, while ulcerative disease of the tricuspid valve is exceptional, it is met with in this particular form of endocarditis, and capillary emboli of branches of the pulmonary artery are known to have this origin.

In children, according to Blæhe,\* endocarditis of the right side of the heart is observed as often, if not more frequently, than it is of the left side. But inasmuch as the ulcerative form is rare with children, pulmonary infarcti and abscesses due to this cause are very rarely met with. Dyspnoea, however, combined with congestion of the bronchial mucous membrane, is even more apt to complicate endocarditis in childhood than in maturity. It is but prudent, therefore, in all functional or organic disorders of the lungs, and especially those which come on rapidly, whether it apparently be as idiopathic or as secondary affections, to examine the heart daily, and to note whether or not the endocardium be inflamed. If discovered to be so, an explanation is at once afforded of oppression too considerable to be wholly accounted for by the existing lung disturbance. In rare instances, after Sibson, † pulmonary apoplexy or extravasation is the result of difficulty of the blood-flow through the lungs, and sanguinolent sputa are expectorated. This condition, of course, indicates absolutely intense capillary congestion of the mucous membrane lining the bronchial tubes, and is dependent usually upon the enfeebled state of the cardiac contractions, and a debilitated nerve-force. To increased blood-pressure in small vessels must also be added, in certain cases, the degeneration which their walls have undergone and which increases the tendency to rupture. ‡ Passive congestion due to endocarditis may not, however, either end in the extravasation of pure blood from over-tense vessels, or remain limited to this condition. It may progress and terminate in solidification of lung tissue. And this is made evident, partly by the local signs of condensation, partly by sudden increased dyspnoea and rusty expectoration. It has been doubted by some whether pneumonia should be considered a complication of endocarditis in any event. This I cannot understand, for it appears to me quite as rational that pneumonia should follow endocarditis, as that pneumonia should be followed by it. Of course I would eliminate from consideration those instances in which pneumonia existed prior to the evident début of endocarditis. There still remain cases in large number where pneumonia has been revealed at the same time with signs of endocarditis, and others, also, where pneumonia followed closely in the wake of this disease. In the first division it may be legitimate to infer that the two localized inflammatory conditions were due to one similar cause. This cause may be the influence of cold, of rheumatism, of the purulent state, of typhic conditions, of pyæmic poisoning. And it

would be difficult sometimes to separate the action of these general causes from a local one, and to show reasons for belief that pneumonia was due to endocarditis and not to what evidently produced the inflammatory condition of the heart. Again, there are numerous examples where pneumonia was developed subsequently to endocarditis. This is often seen in acute rheumatism, and, according to Fuller,\* we should even then understand it to be occasioned by the general diathetic condition, and not brought on by endocarditis. From what I have been able to observe, I cannot subscribe to this view. For I have difficulty in explaining how it is that the lung trouble delays its invasion till the rheumatic attack has considerably diminished in intensity and acuteness; how it is that endocarditis, which is quite sufficient, when no rheumatic dyscrasia exists, to cause dyspnoea, congestion, apoplexy, or inflammation of the pulmonary structure, should not continue to exert a similar influence though rheumatism be present, and when the march of morbid symptoms points so manifestly to this interpretation. It has been noted, it is true, by more than one writer, that pneumonia is more apt to follow endocarditis developed in dynamic conditions, or those in which systemic blood-poisoning was undoubted, and under these circumstances the pneumonic process was not frank in its symptoms or morbid aspect. The chill which marks its invasion ordinarily was absent, as also the characteristic sputa. And upon section of lung tissue after death, it was found to be of more diffident consistence and of less granulated appearance than in a typical inflammatory process of acute type. These facts have their weight, I freely concede, but should not make us unmindful of the preceding local condition of the endocardium, which can scarcely fail to help greatly the pathological development in the lungs. Besides, we should not lose sight of the fact that it is precisely in these conditions of the system marked so fully by symptoms of profound and rapid depression that ulcerative endocarditis usually appears.

II. In the commencement of an attack of pericarditis there is probably no rational symptom which has more importance in making one's diagnosis than the existence of dyspnoea in a notable degree. Of course, like other symptoms which are not essential in character, its value will vary—first, with attendant circumstances; second, with the intensity of the symptom itself. If, for example, during a rheumatic attack, difficulty of breathing should manifest itself and upon auscultation of the lungs we find signs either of bronchitis, pleurisy, or pneumonia, we are satisfied as to the cause of troubled breathing, and may not look further, or if we do, and listen to the heart-sounds, their characters are not removed enough from the normal to make us suspect disease of this organ. But let us suppose during a similar attack auscultation of the lungs remains negative, or the pulmonary lesion is slight and the oppression intense, then we listen to the heart-sounds more carefully and repeatedly, and soon physical signs will reveal to us the existence of pericardial inflammation. And if this be true in the case of adults, it is even more correct with children, inasmuch as acute dyspnoea in them, when no pulmonary lesion prevails, is nearly pathognomonic of pericarditis. Formerly great emphasis was placed upon the characters of dyspnoea. Rarely, if ever, it was affirmed, would a patient suffering from simple pericarditis find himself compelled to assume a special posture. He could move his body in

any way he chose; from a dorsal decubitus to a lateral one, from a recumbent position to an erect one, and yet in these different changes his breathing remained the same, was not notably accelerated or oppressed in any one of them. On the other hand, if orthopnoea took place rapidly, or slowly; if the patient were re-awakened in the early part of the night after a few hours' sleep, feeling as if he were stifling from lack of air, with palpitations and precordial anxiety, these symptoms were pathognomonic rather of an inflamed pleura than of an inflamed pericardium. In our day we no longer attribute so much importance to the mere rational signs of disease; we are more apt to pin our faith to physical signs, and perhaps after this manner to lose sight at times of the knowledge which ancient observation has handed down to us. What, we may ask, are the causes of dyspnoea in pericarditis, and why does it vary in intensity with different patients? In replying to this question we should consider, 1st, the morbid conditions of the pericardium; 2d, the complications which accompany these conditions. Whenever the pericardium is acutely inflamed, it may remain in a state where plastic exudation of a more or less extensive area is the only lesion that morbid anatomy shows, or liquid of serous or purulent nature in small or large quantity may become effused into its cavity. In the first category we find a certain number of instances, and these are not marked by dyspnoea unless the exudative material be so considerable in extent as to bind the heart muscle, and thus, by giving rise to heart-clot,\* form an obstacle to its normal and healthy contractility. Such examples are met with in chronic forms, but scarcely ever in acute stages of this disease. Now, if effusion be established, it may be in small amount, and even this quantity may form by degrees. Then the heart continues to act very much as before it took place, and the respiration is not appreciably affected—but let the effusion become large, and what results? In the first place, breathing becomes difficult when the patient is in the dorsal decubitus, for in this position the pericardial effusion gravitates towards the base of its enclosing sac, and there exercises a compression upon the large vessels which trammels the blood-flow. The patient, in order to get relief, will lie on the left side, and in instances of excessive effusion will be forced to assume a sitting posture. By the first change of position the right lung is allowed to inspire air more freely; if the second be taken the greater quantity of fluid falls towards the anterior chest walls, and thus both the lungs and great vessels at the base of the heart are liberated in great measure from pressure. Owing to the relative position of the heart within the thoracic cavity, the left lung is always more compressed than the right, and it is to this compression that is in great part due the oppression from which the patient suffers. But this is not all, for at times the left pneumogastric trunk is stretched, and from irritation thus produced we may have spasmodic contraction of the bronchial tubes and increased anxiety. The dyspnoea may depend not upon the pericarditis properly speaking, but upon a complication arising within the heart or elsewhere. In the former case, endocarditis or myocarditis is ordinarily developed; in the latter, neighboring organs are implicated by the extension of the inflammatory process. The diaphragm may become inflamed and paralysis of this muscle be effected. The result of this condition is to augment oppression, to render chest movements shorter and more rapid, and the reflex actions of cough and expectoration very difficult.

\* On Rheumatism, Rheumatic Gout, and Sciatica, 1:54.

\* Luequy. Des concrétions sanguines, 1863.

Under these circumstances we can appreciate how even a slight pulmonary disorder may involve a grave prognosis. By reason of contiguity and resemblance of structure pleuritis frequently follows pericarditis. And so true is it, that recommendable authors affirm whenever pain and dyspnoea are present they are invariably due to pleuritic complication. This statement is obviously incorrect, since spontaneous cases of pericarditis, in which no concomitant lesion exists, are accompanied by these symptoms. But that they are both augmented, and particularly the difficulty of breathing, by intercurrent pleuritis, cannot be questioned.

Pneumonia may be due to propagation of the inflammatory condition from the pericardial sac, and it may also be present together with pleuritis, produced after a like manner. Frequently, however, pneumonia is occasioned by the dyscrasic influence which has likewise been efficient in causing pericarditis, or else is the variety attributable to capillary embolisms originating in an inflamed endocardium, but only manifesting itself after some days' duration of disease. No doubt, when a large effusion exists in the pericardium, and the left lung is compressed, there is predisposition to congestion and inflammation of its structure. Of course in pericarditis this tendency is still further increased by compression of the heart muscle and embarrassment of its functional activity.

III. The symptoms of myocarditis are ordinarily obscure, and we are unable during life to make an exact diagnosis. In those instances, however, where we are likely to encounter this complication, and where without premonition the heart-sounds and pulse rapidly become feeble and irregular, and the respiration greatly obstructed, with frequent, paroxysmal cough, some frothy sputa, lividity and coldness of the extremities, and upon auscultation of the lungs stethoscopic signs of engorgement or oedema are discovered, we are right to conclude that myocarditis has become developed. Of all these symptoms there is none more marked or important to consider properly than the sudden dyspnoea. Difficult, oppressed breathing is in these cases significant in a high degree of impaired heart-power, and no doubt more so in reality than of what is usually accepted by the term "inflammatory condition." It is pronounced and distinctive, and yet if the lungs be carefully ausculted during the first few days of disease, we cannot detect pulmonary lesions which are sufficient to account for the distressing anxiety shown by the aspect of our patient. During a more advanced stage, mechanical obstruction and its rational phenomena are accompanied by moist râles disseminated throughout the chest. Rarely, signs of pleuritic effusion, or those of incipient pneumonia, are discovered. According to my own belief these various symptoms and conditions are under the dependence of irregular and weakened cardiac action occasioned by atrophic or fatty degeneration, which leads directly to venous stasis in the pulmonary circulation.

Perhaps pressure upon interstitial nerve filaments should explain painful symptoms of persistent, though spasmodic type, felt at one time in the præcordia, at another in the lungs.

From what precedes, can we deduce some valuable notions of treatment? Doubtless when fever is intense in pulmonary complications dependent upon acute cardiac disease, it is proper to make use of local antiphlogistic or counter-irritant treatment.

Anodyne poultices, compresses wet with cold water, iodine, blisters, etc., applied over the chest in different regions according to the evident indications of each case, are useful adjuncts, and diminution of inflamma-

tion, stimulation of heart-power, and absorption of exudations, may thus in a measure be effected. And yet it is admitted by almost every practitioner of medicine that general remedies are those which should inspire us with most confidence. Amongst them we have usually looked to the antipyretic class as the one where we should find suitable drugs to combat successfully the symptoms which are here noteworthy. Those most employed are quinine, aconite, opium and its alkaloids, veratrine, belladonna, aided by soda and other alkaline salts, if a rheumatic diathesis is found to be present. Quinine especially is our mainstay. Quinine, it is said, is most useful in diminishing fever; it lessens rapidity of the pulse, it decreases arterial tension, it destroys cell proliferation, it is antiseptic and highly tonic in its action. How far is this accepted belief correct, and to what extent shall we trust quinine in conditions similar to those described?

*First.*—Quinine, like the majority if not all drugs, acts very differently according to the dose which is administered. If given in small doses, one to two or three grains, it is a tonic, but only a poor or very moderate one even then, for in its tonic action it is far surpassed by bark itself, by its tincture and fluid extract, and by other remedies, such as iron, strychnia, phosphorus, and arsenic. Quinine, let it be well understood, is not the essence of Peruvian bark, but one of many elements contained in it, and while the latter substance since its first use has been invariably credited with corroborating effects, the physiological action of the pure alkaloid has been much watched and debated by experimenters, and the observations published are by no means in accord. From the different results published has arisen various practice. The Germans give quinine in moderate doses as an excellent tonic, in very large ones as a most effective antipyretic remedy.

This view has been accepted, generally and entirely, by English and American, but not by French, practitioners of medicine. For while the French consider quinine when given in large doses to be very useful in reducing temperature, they do not regard it as being a tonic agent of great value in small ones.

*Second.*—The question of the antiseptic power of quinine has been discussed by me already at length, in a paper written in the *American Journal of Obstetrics*, June, 1876, on the so-called antiseptic treatment of diphtheria. I there endeavored to show that even though we frankly admit the power which quinine with certain other well-known drugs (carbolic, salicylic acid, etc.), evidently possesses, in a certain measure, to lessen the vitality of lower organisms when brought into contact with them, under the form of powder, or of concentrated solution, there is no fair reasoning which will permit us to assume that quinine, given internally in moderate doses, as it usually is, will affect in the smallest degree the poisonous entities of infectious disease.

*Third.*—The power quinine has to destroy cell proliferation, more particularly in pneumonia and in phthisis, has been strongly defended by a very able professor in our midst, and I naturally feel some hesitancy in combating this doctrine. Nor do I directly. I would merely proffer another explanation, *i. e.*, that in pneumonia and phthisis cell proliferation is not, as it were, one of the immediate and necessary consequences of inflammatory conditions of lung tissue considered as such, but rather of stagnation of blood in the capillary circulation, no matter *where* or *how* brought about. Now in all cases where inflammatory phenomena are pronounced, and especially where temperature ranges very high, and lowering of bodily heat

even temporarily is a primary indication, the use of quinine in fairly large doses is commendable. 1. Because combustion is then very exaggerated and of course waste material accumulates everywhere, and perhaps nowhere more abundantly than upon the pulmonary mucous lining when it has become the seat of morbid action. 2. If temperature be lowered, oxygenation of blood and tissue is less active, and cell proliferation consequently less abundant.

In those instances, therefore, where pneumonia is a very active inflammatory disease, no doubt Prof. Loomis is correct in his belief with respect to quinine and its action. But in those cases where pneumonia or bronchitis is a secondary disease, where the cause of its production seems to be far less, if at all—the original inflammatory action beginning in its structure—than the mechanical obstruction which proceeds from or is occasioned by a neighboring organ, I do not see a sufficient object to be attained by giving quinine while the temperature of the body in the primary disease is only moderate in degree, and shows but slight increase when the pulmonary complication arises. During last winter I had two cases under my care at Charity Hospital which corroborated this view; one of capillary bronchitis in a man about 50 years of age, the other of pneumonia in a man 40 years of age. In both instances, the patients, when seen by me, were under treatment with large doses of quinine, though the elevation of temperature had been and was moderate. Their hearts had, however, diminished in strength, and were beating irregularly at the rate of 100 to 110 a minute. Respiration was anxious and laborious. The general symptoms were alarming and my prognosis was serious. I changed the treatment to one of large doses of digitalis, and within twenty-four hours had the satisfaction of noting a great amelioration of physical condition in either instance. This fortunate change I attributed directly to increased heart stimulation.

*Fourth.*—It is said quinine diminishes febrile phenomena in lowering temperature and reducing arterial tension and the number of pulsations. Of the truth of this affirmation there can be no doubt. But how does it accomplish this result? Is it not in great part through its weakening action upon the heart? I do not propose to discuss this question from a physiological standpoint—although even then the fact could be readily substantiated by the experiments of Giacomini, Briquet, Binz, Cherone, and others still—but from a clinical one, where I am equally convinced of the exactness of my proposition.

Somewhat more than one year ago, I attended a girl 20 years of age, who was dying rapidly of catarrhal phthisis. Her temperature rose to 103° or 104°. There was sufficient reason to give quinine, which I did in doses of 5 grains, *ter in die*, speedily augmented to 10 and 15 grains morning and evening. Temperature fell, but with this fall the strength suddenly failed, so as to occasion attacks of syncope. Quinine was then interrupted, temperature again became elevated, but strength returned in a measure, and the fainting attacks were at once arrested. I have also apparently noticed this same action, though in a less degree, in one case of pure functional trouble of the heart, and in one of diphtheria affecting a child.

In almost all cases of simple endocarditis and pericarditis, and in many of those where we are right in assuming secondary myocarditis to be present, general treatment with digitalis is the only proper and efficient one to institute from the very beginning of the disease. It increases notably the force of cardiac contractions, and augments arterial tension all over the body; it

lowers pulse, respiration, and temperature, little by little, and without affecting the general tone or strength of the patient in an unfavorable manner. In the treatment of cases similar to those we have considered in this paper, I believe it will be found to be altogether the safest and most trustworthy drug we possess. Its diuretic action, too, can but be most useful by ridding the body of its superabundance of waste material. If the inflammatory condition of the heart be seen from its commencement, I would counsel to be taken from 5 to 15 drops of the tincture, or ʒi. to ʒiij. of the infusion, three or four times in twenty-four hours. At first it may be given alone. After a few days, in the event of any great degree of prostration manifesting itself, let it be combined with Huxham's tincture of bark, or small doses of strychnia, or with both. If, on the other hand, the patient be seen only when there are already evidences of an obstruction of the pulmonary circulation intense in its character, and whether it become apparent as simple congestion, generalized bronchitis, oedema, or any one of these associated with pneumonia, pleurisy, or suffocative catarrh, do not hesitate to administer teaspoonful doses of the tincture of digitalis at intervals of four hours, until anxiety, precordial oppression, and very pronounced dyspnea have partially, or to a great extent, disappeared. If temperature be elevated it will fall soon enough under these repeated large doses, and if it be but moderate—100°, 101°, 102°, Fahrenheit scale—this symptom is not the important one, nor should we have any solicitude concerning it. Rise of temperature, even when exaggerated in acute disease, is not in reality the sole and all-important factor in determining our therapeutic measures. For are we not constantly reminded of this by cases of scarlatina and typhoid fever daily recorded in medical journals, which show no grave symptoms, and yet during their march have had a more or less constant and high range of temperatures? In others, temperature has remained low, and yet many symptoms of aggravated type and seemingly proof of profound constitutional poisoning have developed themselves with fearful celerity. Again, are there not many cases where temperature has remained low during acute stages of disease, and yet ultimate convalescence has been very tedious and marred by many intercurrent accidents of serious import? Once more, then, high temperatures should only cause anxiety when combined with symptoms which also occasion just alarm.

When the other symptoms of acute disease remain of mild type, I, for my part, do not fear those destructive tissue changes which have been the *bête noire* of a host of medical practitioners during the past ten years. Moreover, in considering the appropriate treatment of pulmonary complications of acute cardiac troubles, we should not ignore the results of experiments performed upon animals. Notably amongst practical physiologists, E. Cyon,\* in his work "On the Influence of Changes of Temperature on the Number, Duration, and Strength of the Beats of the Heart," has shown that although during a gradual rise of temperatures cardiac contractions are rendered somewhat more frequent and stronger, yet that at a certain degree of heat elevation their number decreased suddenly and they became rapidly weaker and more irregular, until finally they ceased altogether. Nor was the degree of elevation always invariable nor great in itself. At times, and in some animals, and under similar circumstances, the arrest of the heart-beats took

\* Berichte über die Verhandlungen der K. Sachs. Gesellschaft den Wissenschaften, 1866, XVII., 258 ff.

place when the temperature was only slightly elevated, and again a very considerable degree of heat was obtained before any appreciable morbid effects were witnessed upon this organ. It is thus made evident, even in instances where there are few modifying circumstances to be considered, other than the individual peculiarities of different animals of the same species, that high temperatures do not always produce morbid effects alike either in character or degree. When, therefore, as is the case in nearly all pathological conditions of the human body, there are many undetermined factors to be weighed and balanced before an accurate conclusion can be arrived at with respect to the effects of temperature, it behooves us, indeed, to be prudent in our actions. In one person and in a given disease, the dangers resulting from heart paralysis may be comparatively slight; and although body temperature is much elevated above the normal, in another, *ceteris paribus*, these risks become great and imminent. In pulmonary complications of acute heart disease, it therefore appears to me rational to combat the rise of temperature when it has become elevated to the point of possible danger, especially to the heart, and likewise to the other viscera. But our aim should be to act moderately and with just appreciation of the conditions involved. Temperature may and should be lowered, but only exceptionally by means of agents which will also tend to lower greatly cardiac energy.

If such agents be employed, their use should be restricted within very narrow limits, and never extended beyond the point where their physiological employment terminates. And while making use of any antipyretic remedy, even the safest and most wisely selected one, we should recognize that the sources and mechanism of fever are not yet accurately determined, and there are still many elements pertaining to its origin and development which would greatly influence our therapeutic opinions and action were they more fully known to us.

Rapidity of pulse and respiration are not always the consequences of high temperature, but are occasioned by some other obscure or latent cause, which is possibly the very essential primary factor of rapid febrile tissue changes, and which abnormally affects, at nearly the same time, pulse, respiration, and temperature. All three of these symptoms are then closely correlated, but not of necessity interdependent; and it is very important to render this fact present and clear to the minds of our medical brethren.

In conclusion, I believe the following propositions are fairly established by the reasoning and facts contained in this paper:

1. Pulmonary disorders are frequently the immediate and almost necessary consequence of disordered heart-action of acute type.
2. These pulmonary complications should not be considered as being frequently of inflammatory nature, but rather as being manifestly produced by mechanical obstruction.
3. In our effort to combat effectually these secondary affections, which are often rapidly dangerous, we should make use of a remedy which will strengthen and regularize heart-action, while lowering gradually and safely pulse, respiration, and temperature.
4. Quinine in small or large doses does not produce these results, and should therefore give place to a remedy which does, viz., digitalis.
5. Moderately high temperatures are not necessarily very pernicious or of great moment, in so far as the indications of treatment are concerned.
6. Our therapeutic treatment of pulmonary complications consequent upon acute cardiac disease (endoocarditis, pericarditis, myocarditis) must be guided rather by

the general symptoms of disease in our patient, than by one single morbid phenomenon, viz.: elevation of body temperature.

## A CASE OF GLOSSO-LABIO-LARYNGEAL PARALYSIS.

By ANDREW H. SMITH, M.D.,

OF NEW YORK.

WHILE on a visit in the interior of the State, last August, I saw in consultation a case of glosso-labio-laryngeal paralysis, which, as the disease is rare, may be worth placing on record.

The subject of it was a clergyman, aged sixty-one years. About fifteen years ago, after prolonged and severe exercise of the voice in preaching, he became hoarse, and ultimately his voice failed so that he could speak only in a whisper.

After the lapse of a year he gradually regained the use of the larynx, but as he did so he became sensible of an imperfection in his enunciation of certain syllables, especially those containing the letters p, t, d, s, etc. This difficulty has increased until now the power of uttering the labial and lingual sounds is almost entirely lost.

Later a difficulty in swallowing was gradually developed, which has reached such a degree that only *warm fluids* can be taken, and these with great care and hesitation, as they are apt to cause strangling, and to return through the nose. Mucus accumulates in the fauces, which he has great difficulty in getting rid of, and which causes a sense of strangulation.

He finds that the movements of the tongue are very much restricted, and he has not the full control of his lips.

His sight, taste, and smell are as perfect as is usual in persons of his age. The sense of touch, even in the paralyzed parts, is not impaired.

He feels much less distress when the weather is warm, and dreads the approach of each winter.

Such is the account which the patient—a very intelligent man—gave of himself. As to the objective appearances, the patient moved slowly and feebly, but this was evidently the result of mere debility. The next notable thing at a cursory glance was the expression of his mouth. The orbicularis muscle was entirely paralyzed, permitting the lower lip to fall away from the upper, and to become partly everted. There was also relaxation and eversion of the upper lip from the same cause. The levatores menti and the depressores ang. oris were not involved in the paralysis, and by their aid the patient was able to bring the lips into contact; but when so approximated they projected forward, leaving a space between them and the teeth, and giving a very peculiar expression to the face.

When the mouth was opened the movements of the tongue were observed to be very slow and very much restricted. The tip could not be turned upward to touch the roof of the mouth, nor backward beyond the bicuspid teeth. The tongue was not notably changed in shape or size.

All the muscles of the soft palate, including the palato-pharyngi and palato-glossi, were paralyzed so that when the head was thrown backward the relaxed velum fell of its own weight against the posterior wall of the pharynx. The finger carried into the fauces produced scarcely any local reflex action, showing that the constrictors were complicated; but sensation was perfect, and the reflex action of the stomach seemed unimpaired, efforts at vomiting being readily excited.

There was a very profuse secretion of mucus from the larynx and pharynx, which was gotten rid of with the utmost difficulty. There being perfect inability to contract the cavity of the pharynx, the air which was forced from the larynx in the act of hawking escaped into a great loose bag, instead of into a narrow, firm passage, and thus it failed to drive the mucus before it. The paralysis of the soft palate added to the difficulty, for when by great labor a portion of mucus was coughed up into the back part of the mouth, the non-closure of the isthmus faucium permitted it to fall back again upon the larynx.

Examination with the mirror showed that the laryngeal muscles retained their activity, and the cords, with the exception of slight hyperæmia, were normal. The respiratory muscles were as yet unimpaired.

In this case it is not probable that the loss of voice, which occurred in the early stage of the disease, was owing to a central lesion, since, after a year had passed, the larynx gradually regained its power. Moreover, laryngeal paralysis of bulbar origin does not usually occur in this association until after the paralysis of the lips, tongue, and soft palate has become well-marked. It is more than probable that the aphonia was the result of a catarrhal affection, and that if life continues long enough there will be a return, but this time from advancing changes in the medulla.

The greater ease in swallowing *warm* fluids is characteristic of dysphagia from almost any cause. Thus it is observed in both organic and spasmodic stricture of the œsophagus, and also when dysphagia results from the pressure of a tumor.

## Clinical Lecture.

### FISSURE OF THE RECTUM.

CLINICAL REMARKS MADE AT BELLEVUE HOSPITAL.

By ERSKINE MASON, M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

(Reported for THE MEDICAL RECORD.)

GENTLEMEN:—The patient now before you is suffering from an affection which in itself is very slight, but one that is sometimes attended by most distressing symptoms—she has fissure of the rectum.

Patients suffering from the disease usually complain of a severe burning pain, occurring most commonly a few minutes after having a movement from the bowels, and especially if the fæces are at all hardened. This pain may last for hours and give the patient very great distress. It is probably the single symptom which is most characteristic of the affection, and is sufficient to warrant a most careful search for fissure of the rectum.

A common cause of this trouble is constipation. Under such circumstances, when an evacuation from the bowels does occur, it may be large, the hardened mass perhaps tears the mucous membrane, and a fissure is established. On the other hand, fissure of the rectum may follow an attack of diarrhœa. Again, these fissures sometimes result from specific disease.

They may be situated directly opposite the coccyx, or towards the perineal region, or upon either side of the rectum.

It is not unfrequently the case that patients suffer from this affection for a long time before they seek relief. They suppose that they are suffering from

piles, and when they come to you for advice and describe their case, unless you are upon your guard, it may be mistaken for one of hemorrhoids, and a useless recommendation made. It frequently happens with fissure of the rectum that more or less of blood is lost with each movement from the bowels. That fact alone may tend to lead you astray, and bring you to the conclusion that the case is one of bleeding piles. Again, when you make an examination, you will frequently find the integument along the side of the fissure inflamed and œdematous, and a superficial investigation may lead you to the conclusion that the patient is suffering from an inflamed external hemorrhoid. The only manner, however, in which you will be able to make a correct diagnosis, is by a careful and complete examination.

As you examine these cases, you will almost invariably find associated with the fissure a little papillary enlargement which may have the appearance of a polypus. This polypoid appearance is due to simple hypertrophy of one or two papillæ in the neighborhood of the fissure. These enlarged papillæ may overlap the fissure, if it be a small one, and so conceal it from view. It is important, therefore, in your examination, if such a growth is present, to turn it to one side, and then may be exposed a slight fissure or crack, or grayish line in the mucous membrane that had previously escaped notice. This affection has also received the name of ulcer of the rectum.

The diagnosis having been made, the question arises, how shall the fissure be treated? Can it be treated successfully without resorting to operative procedure?

#### TREATMENT WITHOUT OPERATION.

In young subjects, and where the fissure is of recent origin, you can, in many cases, succeed in curing them without an operation. The treatment is to keep the bowels in a soluble condition, and make use of some astringent and sedative application. A very common prescription for this purpose contains zinc or stramonium ointment in combination with belladonna or opium. This plan of treatment is often followed by complete relief.

There are many persons who are remarkably timid when anything like operative interference is suggested, and you will be able to relieve a goodly number of such cases by pencilling the fissure to its bottom with a fine point of nitrate of silver, or with nitric acid. These applications relieve the pain, because they destroy the little filament of nerve which is exposed in the fissure.

In those cases in which the fissure has attained some size, you can always with the probe find one spot which is excessively tender, and when the nerve exposed at that point is destroyed by the use of any caustic, or by stretching the sphincter, the patient will be relieved.

#### RADICAL TREATMENT.

What is the radical treatment of this painful affection? It consists in dividing the mucous membrane and some of the fibres of the sphincter muscle with a knife. The object is to divide the filament of nerve involved, and, at the same time to put the parts in a complete state of rest. If the nerve-filament is left exposed, all the efforts made by nature towards effecting a cure are frustrated, because every time it is touched by the passage of faecal matter the sphincter is thrown into spasmodic action, and the reparative process is destroyed. If the nerve is destroyed, and the parts put to sleep, as it were, the fissure is quickly

cured. This can be accomplished in two ways. *First*, by over-distention of the rectum. Introduce your thumbs, back to back, into the rectum, make forcible distention towards the tuber ischii, and carry it to the fullest extent possible. In that manner you will completely paralyze the sphincter, if the distention is done thoroughly, and perfect recovery usually follows. There is some danger, however, attending this operation, for you may lacerate the mucous membrane, or you may rupture some vein of considerable size which may give rise to troublesome hemorrhage. Such accidents are not common, but they may occur. The *second* way in which the nerve-filament in the fissure can be destroyed and the parts put at rest, is by means of a cutting operation. In performing this, you should always remove the little enlargement of papillæ which so commonly is present by the side of the fissure, for if you do not, the chances are that your operation will be a failure. The operation itself is very simple, and consists in this. Put the parts upon a stretch by introducing a speculum; the speculum is to be preferred to the fingers. When the parts have been moderately tense, simply draw your knife through the base of the fissure, and divide a few of the fibres of the sphincter muscle; it is not necessary to divide the muscle completely, but simply a few fibres. In this manner you divide the ulcerated mucous membrane, the irritated filament of nerve, and more or less of the fibres of the sphincter below, so that the parts are placed at rest. All that is necessary in the way of after-treatment is, to keep the patient in bed a day or two, and keep the bowels quiet. Before permitting the bowels to move, it is well to give an enema of sweet oil, or some gentle laxative.

#### FISTULA AND FISSURE.

You will recollect I told you that in some cases the integument by the side of the fissure would be inflamed and oedematous, and perhaps to such an extent as to give it the appearance of an inflamed external hemorrhoid. This irritation and inflammation may go on until an abscess is developed. Such an abscess will burst, and when you make an examination it may be found that there is a small fistula formed. The point to which I wish to direct your attention is this: if you are not thorough in your examination, you may operate upon the fistula only, and the patient will probably be cured of it, but the same agonizing pain will continue to be experienced after every evacuation from the bowels, simply because the fissure has escaped observation, and has not been cured. It occasionally happens that several fissures are present, and the question will arise—how are they to be managed? Is it necessary to cut all of them? It is not necessary to divide them all, for if one is thoroughly divided, the sphincter will be placed at rest, and the others will heal very readily.

[The fissure was exposed, and the cutting operation performed.]

**NITRITE OF AMYL IN CHLOROFORM POISONING.**—**SIR:** The subscriber would be obliged if physicians who have had cases in which nitrite of amyl was used to avert chloroform poisoning, would kindly send him notes of them, as he wishes to collect such cases for publication.—**F. A. BURRALL, M.D.**, 28 West 11th st., New York.

**SCHOOL HYGIENE.**—In the discussion on Dr. Loring's paper, Dr. O'Sullivan stated that the *primary* departments of the public schools were overcrowded, but usually not the grammar departments.

## Progress of Medical Science.

**RECENT VIEWS ON INTERNAL URETHROTOMY.**—Mr. Teevan's views, as given before the Surgical Section of the British Medical Association, were as follows: Most strictures are best treated by gradual dilatation with soft bougies, and an operation is only called for in certain exceptional cases. Operations on the urethra may be divided into two kinds: 1. Those which cut through a stricture. 2. Those which tear it open, as in the operation of so-called "immediate dilatation." The object of the operation is to insert a new piece of tissue, "the cicatricial slice," into the constricted urethra. The cicatrix which follows a laceration possesses the maximum amount of contraction, whereas, that which forms after a clean cut has only the minimum degree. Hence, a cutting operation is indicated rather than a tearing one. There are four kinds of cutting operations: 1. Scarification. 2. Subcutaneous. 3. External. 4. Internal. Scarification consists in notching the stricture with a four-bladed instrument. It has fallen into disuse because it is insufficient. A stricture must be cut completely through, and not merely notched. External urethrotomy is very rarely required, and then only when strictures are complicated with abscesses or fistule. Subcutaneous urethrotomy is eligible for single strictures, but internal urethrotomy can deal with any number. He has performed the operation thirty-three times, without a single death. According to the statistics of six surgeons, who have done the operation in all one thousand one hundred and ninety-two times, there were but ten deaths. That is, the mortality was very considerably less than one per cent. Mr. Arthur Dunham described a new urethrotome which he has devised to obviate some of the dangers which he thinks are liable to occur from the ordinary cutting instruments now used. The instrument is a tube having a hollow cylindrical handle at the proximate end, and at the distal end an elongated, slightly tapering dove-bulb, with four slits. Sliding within this tube is a second, somewhat longer, and having at its distal end four sharp-edged blades. The bulb having been passed down to the stricture, the blades are made to project through the slits and divide the strictured portion. The advantages of the instrument are: 1. The safety and facility with which it may be used. 2. The exactly limited depth to which the incisions extend. 3. Four incisions of slight depth are made instead of one of comparatively great depth. 4. The healing or cicatrizing process is facilitated. The instrument has been used in twelve cases, and the results so far have been satisfactory. Mr. Edward Lund, the President of the Section, remarked that the majority of cases of stricture can be treated only by dilatation; but dilatation must be repeated. The cases suitable for urethrotomy are the same as those which would otherwise, on the other hand, be submitted to Dr. Syme's operation. The question, therefore, resolved itself into internal *versus* external urethrotomy. If a guide can be passed, internal urethrotomy contrasts favorably with external urethrotomy. The next question is whether it is better to cut from behind forward, or from before backward. In cutting from before backward, it is possible to deal with finer instruments than in cutting from behind forward. He questioned whether the blade in Dunham's instrument would go far enough into the tissues beneath the cicatrix; moreover, as the cicatricial tissue does

not extend all around the urethra, the instrument cuts wider than need be. He thought it well, before proceeding to any operation, to pass gradually from fine to larger instruments before cutting at all. It was better not to keep the catheter in the bladder. Urethritis and other bad consequences were apt to follow. Splitting a stricture was not so good as urethrotomy; internal urethrotomy was better than perineal section, and to cut only in one place was better than in four, as, after healing took place, there remained but one cicatricial splice. Mr. Berkeley Hill stated that internal urethrotomy should only be employed in the comparatively small number of cases where experience has shown that gradual dilatation has failed to obtain lasting or satisfactory widening of the strictured parts. He would separate strictures into *penile*, or those situated in the pendulous portion of the penis; and subpubic, or those mainly situated in the bulb, and reaching to the membranous portions of the urethra. Penile strictures were most commonly resilient; they dilated easily, but almost as readily shrank back if treatment were intermitted. Division of such strictures had a more lasting effect and saved the patient from the trouble and irritation attending the constant passage of a bougie, though he was not saved by incision, any more than by any other plan of treatment, the necessity for occasionally passing a full-sized sound or bougie to prevent slow recontraction. Again, incision of the penile urethra by a sharp edge was only rarely followed by any injurious consequence. It was in that locality emphatically a safe procedure. Subpubic strictures, on the other hand, when but moderately developed, most slowly contracted after gradual dilatation, and were generally maintained of full patency by the occasional passage of the bougie once a month or quarter, or twice a year. Some strictures in this region depend generally on a large production of fibrous and elastic tissue. Such narrowings are very slow to dilate, and in doing this, great local irritation and distress is often caused. Incision is most suitable in such cases, to be done internally when possible; and cases where the external operation by button-hole incision is needed, he could not believe to be otherwise than most rare. Internal incision of subpubic stricture, caused by a copious fibrous thickening of the wall of the urethra, was deprived of much danger by the thickening itself. The cutting edge might be carried through such tissue safely without fear of its reaching to the vascular parts beyond. Thus, strictures that might be properly cut were the resilient or rapidly recontracting strictures, and the narrow tortuous ones, where a large amount of fibrous tissue existed. Mr. Hill expressed his conviction that there is no real "cure" for stricture. However treated, it will contract unless occasionally sounded. As an instance, he narrated the case of a patient who came to him from South Africa for treatment. The anterior portion of the urethra, which was perfectly normal, admitted a sound of thirty-eight millimetres circumference (one inch and a half), and after urethrotomy was performed, this instrument passed into the bladder. The patient left England using a bougie of thirty-two millimetres circumference, and in time reported complete recovery. Lately, however, Mr. Hill has received word that the stricture is recontracting, and the patient is expecting to return with the view of having the operation repeated.—*British Med. Jour.*, Sept. 1, 1877.

ATKINSON ON PERINEAL SECTION.—Mr. Atkinson, of Leeds, referring to a statement made last year by a London surgeon, that the *boutonnrière* operation, or per-

ineal section, was performed frequently and systematically at Leeds, said that in the infirmary of that town alone, thirty-nine cases had been operated on during the last three years. The mortality was seven, or about eighteen per cent. Of his own cases, two were desperate; in one, extravasation of urine had taken place, and in the other there were abscesses in the scrotum and perineum; both of them died. Of the remaining seven, all did well. Mr. Atkinson related one case in which the patient, though cured, lost the ejaculatory power *in coitu*. The cause was not ascribed to the notching of the accelerator muscle, which Küss, of Strassburg, has shown to be not the real agent of ejaculation, but the division of the nerves of the membranous portions.—*Brit. Med. Jour.*, Sept. 1, 1877.

ANURIA LASTING TWENTY-FIVE DAYS—RECOVERY.—The following extraordinary case, occurring as a sequela of scarlet fever, is reported by Dr. Wm. Whitelaw. The subject was a healthy boy of eight. December 3d, his urine was observed to be scantier than usual, and the amount decreased rapidly until the 7th, when only one drachm was passed, and from this date up to the 21st, not a single drop, and yet with the exception of a slight headache his general health was excellent. During this time diuretics and diaphoretics were tried without effect; on the 19th a blister was applied over the kidneys, and in twenty hours two ounces of urine were passed, when complete suppression again occurred. The blister was reapplied on the 27th, but with no success. Diaphoretics and purgatives were now discontinued in the hope of forcing the kidneys to act, but no change became apparent in the condition of the patient, who still continued in excellent health. On December 31st very slight œdema of the feet and ankles appeared; and on the morning of January 2d, one drachm of urine was passed. On the same day electricity was applied to the spine, and through the kidneys, and a small catheter passed into the bladder, in the hope of exciting reflex action. On the 3d and 4th of January about the same quantity of urine was passed daily, and on the 5th, a whole pint was voided in small quantities at eight different times. Since then the kidneys have acted well, and the boy has (January 12th) recovered.—*The Lancet*, Sept. 29th.

RELATION BETWEEN URINARY SECRETION AND IRRITATION OF SPERMATIC PLEXUSES.—M. NÉPCEU read a paper at the Havre meeting of the French Association for the Advancement of Sciences, in which he gave the results of his continued researches on the variations which the urinary secretion may undergo as a consequence of various traumatisms. He has arrived at the conclusion that the testis may, in certain abnormal conditions (such, for example, as follow injections of iodine into the tunica vaginalis, and in neurosis of the testis), be the starting point of reflex actions affecting the urinary secretion. This reflex action, especially when caused by injections of iodine into the tunica vaginalis, is exhibited by a series of oscillations in the secretion, the first effect being oliguria, which lasts for some days, and is followed by polyuria, succeeded by a return to the normal condition. This result of the injection of iodized solutions into the tunica vaginalis may be regarded, M. NÉPCEU thinks, as an experiment which establishes the reality of physiological connection between the renal secretion and the irritation affecting the spermatic plexuses.—*The Lancet*, Oct. 6th.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

## MEDICAL MEN IN RELATION TO LEGAL TESTIMONY.

We seem to be passing through a period when the status of medical men in their relation to testimony given in legal cases is to be placed in a more definite light. The evidence in the Penge affair, in England, will benefit ourselves, if no others, by showing how much value is to be put upon the statements of ordinary practising physicians as to the cause of death, when they make post-mortem examination in obscure cases. Though the law recognizes each and every one of them as experts, it is quite clear that they are often far from being really such in a strictly medical sense. In this country we have just had a little experience of another point in such cases, viz., the relation of medical testimony to the law on the one hand, and a decedent's interest on the other. In an article published in the "World" of Nov. 16th, in reference to the Vanderbilt Will Case, we have noticed that a great display of apparent indignation and alarm was manifested by a writer, who seemed to infer that the medical gentlemen employed by Mr. Vanderbilt during life, or by his friends after his death, have failed to make proper use of their professional privilege in concealment of certain facts about the deceased, which came to their knowledge while performing professional duties. It is implied that their testimony should not have been allowed in a Court of Justice, on the ground of the following statute:

"Section 72. No person duly authorized to practise physic or surgery shall be allowed to disclose any information which he may have acquired in attending any patient in a professional character, and which information was necessary to enable him to prescribe for such patient as a physician, or to do any act for him as a surgeon."

The writer, however, takes care to add that "the prohibition does not apply to an autopsy, but fortu-

nately, unless in cases of suspected crime, an autopsy need not be made, and the friends of the deceased, except in such cases, can protect the surgeon, themselves, and the public." We fail to see how either this statute as it stands, or Sect. 834 in the Code of Civil Procedure, (which is about the same thing), applies to any of the medical gentlemen in the case, and as the writer expressly stated that it "does not apply to an autopsy," it certainly relieves the gentlemen who made this examination from any unpleasant burden which the tenor of the article might have appeared to throw upon them. When, however, the writer adds that "unless in cases of suspected crime an autopsy need not be made," we are afraid that he lays himself open to the charge of ignorance in medical matters, that is almost equal to his ignorance of the operations and purposes of the law. No post-mortems to be made except "in cases of suspected crime," has indeed a sort of ring about it that may commend itself to the false sentimentalism of those who believe that the wretched earthly casement of humanity is religiously inviolate when the breath of life has left it. This is not the view that the physicians hold, either of their patients or friends, and a very large number of our most cultivated people appear to agree with them. There is not a department of medicine in which advances are made with greater rapidity than in pathological investigations upon dead persons, and are we to be satisfied with the results merely that are reached in cases of suspected crime? Do the returns which we get from the investigation of criminal cases lead us to be satisfied in depending on them for our advances in knowledge? Are the drippings from the inquests of coroners or their deputies to appease the demands of science? Are we to be submissive and docile under the teachings of a political ring? No, the truth is that post-mortem examinations are gaining rather than losing in favor, and our best surgeons and physicians demand them as a measure of justice to themselves and for the satisfaction of the friends of the dead.

When medical testimony, as to autopsical revelations, is called for in court there seems to be no good ground for withholding it, and in a probate court contestants as well as proponents have an equal right to it. As a matter of fact in this particular case the proponent's counsel does not seem to have made any formal effort to exclude it, except when first the witnesses objected to testify. And this brings us to the most important point in such testimony, the question whether the medical attendant or employee has a moral right to disclose matters regarding the patient, either before or after death, when his knowledge may have been gained in confidence. It seems to be just here that the higher law comes in, which every conscientious physician will not be tardy to obey, whatever the personal consequences. We have reason to believe that no more

zealous guardian of such confidences can be found than the true physician, in cases where his conscience compels him to be silent, though the law may give him no immunity, and its officers instruct him to disclose. Fortunately, the law recognizes such exceptional cases, and a physician is protected, as in the well-known instance where it is sought to prove the presence of syphilis in a married man in a suit for divorce. In the case of which we speak, the matter seems to have been made sufficiently plain by a decision which governs the rulings of the Surrogate's court.

In the case of *John Harrison's Will* (Allen v. Public Administrator, 1 Bradford, Surrogate Reports, 221), in 1850, it was held that "the provision of the Revised Statutes that a physician shall not be allowed to disclose any information which he may have acquired in attending any patient in a professional character, and which information was necessary to enable him to prescribe for such patient," is not applicable to the physician of a deceased person, in a testamentary cause concerning the probate of the will of such decedent. The statute does not establish a general and absolute prohibition of such testimony in all cases; but secures a personal privilege to the party, not to the witness, which may be waived.

If such privilege does not die with the party, still before administration, in a testamentary proceeding, there is no one competent to assert the privilege in exclusion of testimony necessary to the determination of what constitutes the last will and testament of the deceased; and Surrogate Bradford, in delivering the opinion, said:

"I do not, in the first place, think that testamentary cases are within the reason or the intention of the statute in question; and secondly, if covered by its letter, then the decease of the party puts it beyond possibility to assert the privilege; and if still, from reason of public policy, the court should feel bound to extend and keep alive the privilege, that will not be done any further than is consistent with justice and good morals."

It will be seen by this decision that the whole matter is clear and unmistakable in a legal sense. Surrogate Bradford's opinion, given over twenty years ago, is now in force in the Surrogate's court, and probably will be until set aside by some other and more weighty one. From a legal point of view, we have nothing to say about it. From a moral one its tendency seems to be good rather than otherwise. There seems to be no proper reason for attempting to secrete from the litigants in this case facts which there was no effort made to conceal, and which, indeed, both the family and attending physicians and surgeons desired to have looked into. Nor, in truth, was any special attempt made to withhold the official report of the autopsy from the contestant's lawyers, and they very naturally have sought to make what use of it they could. Whether the public have any right to obtain such information in the

courts of justice is another question, though one of no trifling account. When distinguished persons die, and medical men are asked to investigate the matter closely, they will undoubtedly do so to the extent of their ability, and as we advance in our ways and means of investigation, the examination will be closer, and the facts thus obtained will be brought out in a court of law, if there is litigation.

It is a serious question as affecting public policy whether such purely medical matters should be permitted to appear in the public prints; but this is a point not for physicians, but for legislators, and the journals that take pains to furnish such reports have only themselves to blame for the material they supply to their readers. There is little doubt but that the court would, in general, protect the decedent, in such cases, from testimony tending to defame or degrade his character, and even should it not, no high-minded physician will hesitate for a moment to refuse his testimony in such matters, and he may be sure of being sustained by what is higher than judicial enactments—the verdict of public opinion, and the approval of his professional brethren.

So far then as testimony has been furnished, it seems to have been in no sense "privileged," in a legal sense, nor was it a matter of conscience. The physicians very properly objected to testify, but on the ground that their information was not their own, having been furnished in a professional way to private parties, to whom, therefore, it belonged. The court, however, decided that it did not so belong exclusively to the parties, and instructed the witnesses to testify. Perhaps the law in such a case was thoroughly proper; at any rate, the physicians seem not to have made any statements that could in any way lower or defame the decedent or his family, unless it is a disgrace to be an heir to common physical weaknesses, or to die with a somewhat extraordinary number of pathological lesions.

#### SCARCITY OF DOCTORS IN RUSSIA.

We are informed that there is a great scarcity of medical men in Russia. In fact, since the war, and in consequence of the absence of the large number of Russian surgeons upon the field, the people actually suffer for the want of proper medical attendance. It is owing to this scarcity of medical men that the training of women for medical positions has assumed an importance in Russia which it has not acquired elsewhere. In the present state of overstocking of the medical market in this country, Great Britain, and several parts of Germany, these facts may appear quite startling, but in reality they are not so, when we take into account the high standard of medical education in that country, the small number of medical colleges, and the absence of a "generous rivalry" to graduate large classes. The dearth of doctors can at best be only temporary, as the supply of even first class talent

will be always sufficient to meet any demand for it either in Russia or anywhere else. The only trouble with us here is, that we are getting too much of a stock ahead, and a consequent depreciation of the market value of medical services. In this connection, and as germane to this subject, we would refer our readers to the remarks on some of our present abuses on medical charity, made by Dr. Gibney at a recent meeting of the Medical Journal Association. It is certainly sorrowful to contemplate the immense amount of clinical material as well as paying practice which is now running to waste in Russia.

## Reviews and Notices of Books.

**FORENSIC MEDICINE AND TOXICOLOGY.** By W. BATHURST WOODMAN, M.D., F.R.C.P., Assistant Physician to the London Hospital, Physician to the North-Eastern Hospital for Children, etc.; and CHARLES MEYMOTT TIDY, M.B., F.R.C.S., Professor of Chemistry and of Medical Jurisprudence and Public Health at the London Hospital, etc. Philadelphia: Lindsay & Blakiston. 8vo, pp. 1083.

We have before us a new candidate for favor with the medico-jurists of this country. Its reception in England has been sufficiently gratifying to warrant its republication in this country. Although compressed in one volume, and thus made cheaper than the two volumes of the original English edition, there is the usual drawback of poor paper and indifferent typographical execution. But this is by the way. Of the book itself as a treatise upon a general subject in which every practitioner is interested, we have much to say in the way of praise. Its completeness is its principal recommendation. It is a matter of astonishment to the reader to see how much valuable and accurate information is condensed, comparatively speaking, in such a small compass. There is also a freshness about the make-up of the book which is agreeable to the student accustomed to the other standard treatises. The subject of toxicology justly receives a very extended notice, and leads the student into all the intricacies of chemical analysis, the thorough mastery of which is so important to the expert. In the description of the processes we notice that the strictly scientific nomenclature has been in a measure ignored, but this is evidently done purposely to aid more intelligible consultation on the part of the legal profession. Unlike most works of its class, the subjects are viewed more from the medical than strictly legal standpoint, and we think this an advantage to both professions. From the bewildering number of subjects discussed, it is impossible to name even a few of the many which are specially interesting to the general practitioner, not only from a medico-legal point of view, but from that of scientific study. Adding to the practical interest of the volume there are eight well-executed chromo-lithographs, illustrating respectively stomachs poisoned by arsenic, corrosive sublimate, nitric and oxalic acids, spectra of blood; and three plates on microscopic appearances of human and other hairs. While speaking of blood spectra we are reminded that the article on blood, microscopically considered, is one of more than ordinary interest. Besides the illustrations alluded to above, the text is further embellished with one hundred and fifteen woodcuts. Altogether, the work will rank with the best of its class as

a medico-legal handy-book, and cannot fail to gain a wide popularity.

**THE INDEX OF DISEASES AND THEIR TREATMENT.** By THOMAS HAWKES TANNER, M.D., etc. Second Edition. Revised by W. H. Broadbent, M.D., Fellow of the Royal College of Physicians, etc. Philadelphia: Lindsay & Blakiston. 1877. 8vo, pp. 432.

This work, like others from the gifted author, has already won for itself a reputation. The second edition of the Index, revised by Dr. Broadbent, carries out the original design of the work, and makes it in the highest degree useful to the general and busy practitioner. To those who are not acquainted with the plan of the work, we may say that it is a condensed treatise on the general practice of medicine. When the description and treatment of any given disease is compressed in an ordinary sized paragraph, it is easy to understand what an immense variety of subjects are noticed, and how tersely they are presented. It is in truth, what its title indicates, "*An index of diseases and their treatment.*"

**HANDBUCH UND ATLAS DER TOPOGRAPHISCHEN PERCUSSION.** Von ADOLPH WEIL, Prof. a. d. Universität Heidelberg. Leipzig: F. C. W. Vogel. 1877.

This is the first work devoted solely to the study of topographical percussion in health and disease that has so far been published in Germany. As far as we have been able to learn, no work of the sort has ever appeared in English. The first part of the book is devoted to brief articles on the theory of the percussion note, the methods of percussion, the special rules to be followed in determining the outlines of organs, and on dermatography. The different parenchymatous organs are then considered in detail with regard to their anatomical positions and boundaries both in health and disease. Finally, the alterations in the percussion notes and the topography of the body in several special pathological conditions, viz., pulmonary cavities, emphysema, pneumothorax, exudations into pleural and peritoneal cavities, and meteorism, are fully described. The work is enriched by 26 lithographic plates, on which the outlines of the different organs in health and disease are projected in colored lines. The book is certainly a very valuable contribution to medical literature, but the fact that it is devoted to the consideration of only one branch of physical examination will not be likely to increase its popularity in America.

**THE PHYSICIAN'S VISITING LIST FOR 1878.** Philadelphia: LINDSAY & BLAKISTON, 1878.

Messrs. LINDSAY & BLAKISTON are the first in the field with a visiting list for the coming year. As usual, it is published in good style, with fine paper, good pocket-book cover, and its inside arrangement is the perfection of simplicity. It is now in the twenty-seventh year of its publication, being the first work of its kind issued in this country. A commendable feature of the List is that but two or three leaves are occupied with printed matter, almanacs, antidotes, etc., the remainder being devoted to a systematic record of practice.

**POPULATION OF GERMANY.**—The population of Germany in 1871 was 41,058,792. At the end of the year 1875 it had increased to 42,727,360. The increase was general, but was greater in some states of the empire than in others. In Prussia, for instance, it was greatest, while it was least in Alsace, Lorraine, and Mecklenburg.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, Oct. 10, 1877.*

DR. E. G. JANEWAY, PRESIDENT, IN THE CHAIR.

THE PRESIDENT stated that he had examined the specimen of heart presented a month previously by Dr. Flint, and removed from a gentleman who died without apparent cause, and did not discover enough fatty degeneration to account for the cause of death.

DR. DELAFIELD presented a specimen of fusiform aneurism of the thoracic aorta on behalf of a candidate for admission.

#### OVARIOTOMY DURING PREGNANCY—AN ERROR IN DIAGNOSIS.

DR. ERSKINE MASON presented a uterus which illustrated a blunder in diagnosis, and which on that account he desired to place on record in full. The history was as follows:

A. B., aged 30; Ireland; single; was admitted into Roosevelt Hospital July 30, 1877. Gave the following history: Family history good. Menstruation began at the age of 15; was normal in every way until four years ago. At this time her menses, instead of lasting four or five days, continued but for two days, flowing slightly only the first day. The period, however, between menstruation was the same as before. Since last March, though regular, she has lost less blood, and for the past two months has scarcely had a show. (According to statement she made the members of house staff, who took her history, "for the past two months she did not menstruate at all.") About a year and a half ago she noticed that her abdomen was increasing in size, more particularly on her left side. This enlargement increased very slowly up to last March, since which time it had grown very rapidly. For the past two months she has had trouble in breathing while lying in bed, and for the past two weeks she has been obliged to sit up in a chair at night, on account of difficulty in respiration. Bowels constive, urine passed somewhat more frequently of late, and the amount diminished. For the past four weeks there has been some swelling of the feet. Previous to her present trouble she was a strong, healthy woman. For the past two years she has been losing flesh, more especially during the last eight or nine months. Appetite has become poor, but digestion has remained good.

Her countenance was distinctly that of a woman suffering from ovarian tumor. Upon vaginal examination the mucous membrane of the vagina was of a dark hue, the veins somewhat varicose in places; a good deal of vaginal discharge was also present. The uterus was high up in the pelvis, not readily movable, and the cervix to the touch was neither hard nor very soft, but felt as if eroded. The uterine sound was arrested at the distance of two and three-quarter inches. Physical examination of chest revealed the organs healthy. For the first day after entering the hospital there was a trace of albumen in the urine; this passed away, and repeated examinations failed to reveal casts.

Examination of abdomen revealed a greatly distended abdomen, measuring from one anterior superior spinous process to the other 19½ inches; from either anterior superior spinous process to umbilicus, 10 inches; from ensiform cartilage to pubis, 19½ inches; circumference at umbilicus, 39 inches; circumference just below umbilicus, 38½ inches; at the depression or

groove, presently to be spoken of, 37 inches; percussion of abdomen gave flatness except posteriorly; axillary lines where it is tympanitic; fluctuation distinct, not altered by change in position; more distinct in upper than in lower portion of abdomen; low down in left iliac region fluctuation less distinct, and to the feel seemed as if this were the more solid portion of the cyst. About two inches below the umbilicus there was noticed a distinct depression or groove, which was regarded as indicating the presence of two large sacs, or else due to the pressure of the clothes of the patient.

The case was regarded as one of large ovarian tumor, and one demanding operation. The presence of the congested appearance of the vagina led to the suspicion in the minds of some of the house staff that perhaps the case might be complicated with pregnancy. To me, however, this suspicion did not occur, for I thought I could readily account for the congested appearance of the vagina from the pressure of the large tumor. Again, from examination and from what I had heard of the character of the patient, I had no reason to doubt the truth of the statements she made me. The abdomen, however, was several times carefully auscultated by the house physician, and no evidence of pregnancy discovered.

On the 10th of August, her general condition having improved, at 3.30 P.M. I proceeded in the usual manner to do ovariectomy. Upon opening the cavity of the peritoneum considerable ascitic fluid escaped, and a tumor presented itself at the wound, dark grayish in color, and this was taken to be the more solid portion of the tumor. To the touch it gave the sense of obscure fluctuation. A sound was now passed in, and no adhesions detected, save in left iliac region, and these were slight. The fingers followed the sound, and the same result obtained. Spencer Wells's trocar was now introduced into what was taken for the lower cyst, and about eight ounces of a thin reddish fluid withdrawn. The fluid ceasing to run, the trocar was withdrawn and the finger introduced into the womb, when to my surprise I felt that the trocar had probably entered a pregnant uterus, and that my finger was actually in contact with a placenta. This statement I made at the time, and it was confirmed by the touch of others. The wound in the uterus was speedily closed by catgut sutures; these failing to prevent all bleeding, a silver wire was introduced around the opening and twisted, which prevented further bleeding. The abdominal opening was now enlarged and revealed an enormous ovarian cyst springing from the left ovary, enveloping the upper portion of the uterus, and extending up to the diaphragm, to which it was in close contact. Not being enabled to pass a sound between the tumor and the diaphragm, and being at a loss to determine whether extensive adhesion existed or not, and owing to the injury already inflicted upon the uterus, it was deemed prudent for the present to suspend further proceedings. The wound was accordingly closed with catgut sutures and dressed after Lister's method—the operation itself being done under the carbolic spray. The patient passed rather a restless night, and at 3 A.M. she complained of something coming down in her vagina, though she has complained of no abdominal pain. Upon examination, there was discovered a fetus with its membranes protruding from the vagina; this was removed, and in a few moments it was followed by another with the membranes entire. From examinations of the fetuses it was supposed they were between five and six months. Patient gradually sank, and died at 12.30 P.M., 18½ hours after the operation and 9½ hours after delivery.

*Autopsy.*—Uterus well contracted; peritoneum normal; no blood in peritoneal cavity; a large multilocular cyst arising from left ovary; kidneys congested; other abdominal viscera healthy; silver wire which was passed around opening in uterus had slipped off and was found in front of uterus. No adhesions of sac to abdominal walls were found.

In concluding, Dr. Mason remarked that in the history of ovariectomy similar cases were mentioned. He had no doubt if all those were reported the difficulties in the way of diagnosis would be better appreciated. He believed every care was taken to make a correct diagnosis, although he confessed that the idea of pregnancy did not seriously impress itself upon his mind. Members of the house staff, however, examined her with reference to this point, but failed to discover any signs save blueness of the vagina.

DR. J. C. PETERS expressed thanks to Dr. Mason for the frank manner in which he had reported the case.

DR. JANEWAY remarked that recoveries under such circumstances had taken place.

DR. MASON remarked that if he had been certain no adhesions existed he would have removed the sac at once. Spencer Wells had operated nine times under the same circumstances.

DR. BEVERLEY ROBINSON presented some pinkish albuminous fluids removed from a fibrocystic tumor of the neck by a trochar and canula. The cyst had been punctured on three occasions and injected with tincture of iodine. The result was quite satisfactory.

DR. MASON referred to two similar cases in which the same operation was performed by Dr. Weir with good results.

DR. ABBE presented, on behalf of a candidate for admission, a beautiful collection of specimens, illustrating general carcinosis. Dr. E. C. Seguin demonstrating the different microscopical appearances.

#### PERITONITIS IN CHILDHOOD CAUSING DEATH BY INTESTINAL OBSTRUCTION AT SIXTEEN.

DR. JANEWAY exhibited a specimen removed from the body of a young lady aged sixteen years. Previous to the illness which resulted in her death she enjoyed uninterrupted health from the time she was two years old. The history of her last attack dated four weeks before her death. The symptoms were colicky pains attended with vomiting. The family physician, who was attending her sister for some malarial trouble, had his attention drawn to this patient's case, and, supposing there was also some malarial complication in the case, prescribed for her without seeing her. She became better of this vomiting after a few days, and a fever, which was said to have existed during the attack, disappeared. Exactly a week after the attack she was taken down with the same symptoms, confirming in a measure the previous suspicion regarding malarial origin. After three days she again recuperated, and on the seventh day again presented the same phenomena of symptoms. Another physician was then called, but the diagnosis arrived at was not ascertained. Three days more, there was another partial recovery and another seizure. Dr. Janeway saw the case once after the third relapse. He found her vomiting everything which she swallowed, and complaining of severe colicky pains. By percussion, the large intestine, filled with gas, was easily mapped out. By pressure, this gas was made to move along the canal without apparent arrest or interruption. No tumor was discovered. The patient had passages from the bowels, but they were not free. In the course of a few days again she had another and fourth relapse,

from which she did not recover, vomiting constantly, and dying from sheer exhaustion. Just previous to death she had three involuntary alvine evacuations.

At the autopsy it was found that the small intestine was much shorter than it should be—possibly one-fourth. It was gathered up in quite a mass towards the ileo-caecal valve. There a portion of the intestine, half an inch from the valve, was covered with very thick peritoneum and constricted for a distance of two inches or more. At first this hardened constriction was thought to be an intussusception, but a careful examination proved the contrary. It was caused by the presence of from fifteen to eighteen inches of intestine, looped and curled on itself, beneath this thickened peritoneum. The contraction of this portion of peritoneum, and perhaps, to a certain extent, the growth of the intestine, had brought these fifteen to eighteen inches into two inches. There was a catarrhal inflammation of the small intestine from that point to the stomach, and associated with that condition was considerable dilatation. The constricting band was evidently due to old peritoneal inflammation. Associated with it were old membranous adhesions of spleen and liver to the diaphragm.

The most interesting part of the case has reference to the supposed origin of the peritonitis, which in the end caused her death. In the absence of any other fact bearing upon this point, Dr. Janeway inclined to the opinion that the adhesions and constriction were associated with the sickness at two years of age. At that period the child was believed to have had pneumonia with pleurisy. It was very probable that marked peritonitis was associated with those conditions; that effusion of lymph had taken place around the liver, spleen, and small intestine, and by interfering with the proper functions of the latter, had finally eventuated in death. It may be mentioned in this connection that, for some months before her death, although her appetite was excellent, and she consumed a great deal of food, she did not seem to gain flesh nor develop, as might have been expected. In fact, her intestine, although large enough for a child, and capable of supplying her demands, was unable to meet the emergencies of maturer years, and hence the periodical efforts of nature to strike a balance. The diagnosis made during life was catarrhal gastro-enteritis. There was a suspicion of mechanical obstruction, but it was not confirmed by the ante-mortem examination.

DR. DELAFIELD thought that the explanation was quite satisfactory. The fact was frequently recognized that peritonitis occurs in children without the knowledge of the physician, but the combination of circumstances and the relation of cause and effect in the present case were truly remarkable. It was a striking example of outgrowing one's intestine.

The Society then went into Executive Session.

#### NEW YORK MEDICAL JOURNAL ASSOCIATION.

*Stated Meeting, Nov. 2, 1877.*

DR. J. H. EMERSON IN THE CHAIR.

#### THE MEDICAL PROFESSION AS RELATED TO THE MEDICAL CHARITY ABUSE.

DR. V. P. GIBNEY read an interesting paper upon the above subject. It was assumed that the alarming extent to which the abuse had been carried in the city of New York had been proven. Passing reference was made to the legitimate results of the tolerance of

so great an evil in our midst, namely, suffering entailed upon many young and hard-working physicians, and educating a class of people into respectable pauperism.

When the question was raised, who was to blame for all that? the managers of hospitals and dispensaries threw the entire responsibility upon the medical profession. Indeed, we could accense ourselves of aiding and abetting this gigantic evil. The question, however, naturally arose, how did medical men earn a livelihood? There was an intuitive repugnance to advertising, and besides it was prohibited by the code of ethics. Members of the medical profession, however, did advertise in very many ways. Out of 1,200 physicians belonging to the regular profession in the city of New York, there were found 566 who held positions in the various eleemosynary institutions. Besides these there were a large number of societies and orders which gave advertisement to their physicians on the published pages of their annual reports. Those who did not enjoy such opportunities of displaying their skill as college professors and others must make their money off the general public as best they could. There were many honored members of the profession who were obliged to earn their bread, and hence in the struggle might lie the secret of that suicidal generosity which managers of our public charities in this country and abroad so often placed to our credit.

A legitimate way of advertising was desired by the specialist and by the young man sitting day after day in a lonely office. The clinical professor desired the dispensary appointments for the sake of his assistants, who would generously feed his clinic. Material must be had. On the walls of our dispensaries hung maps, on which were marked the boundaries of the district, and no one was to be regarded as a fit subject for relief unless residing within such limits; yet it was a well-attested fact that a patient in one dispensary district might be under treatment at two or three dispensaries within the same day or week. The doors were now thrown open not only to the inhabitants of the city of New York, but to the dwellers in suburban cities, and even of States near and remote. Now, if any censure was to be attached to the profession, as related to the abuse as it existed in these charities, it certainly must attach to a large proportion in so far as they lent their recognition.

The Doctor then passed to the consideration of hospitals, and spoke of those for the treatment of special diseases as follows: "My impression is that the 'struggling practitioner' of the city, or the country, cries most loudly against the injustice done him here. Men, who have attained an enviable degree of eminence, establish a *high* fee system; then they establish hospitals which shall be as near as possible self-supporting, and give their services gratuitously. A patient applies to them at their office for advice—the advice is given—an operation, say, is advised. Then naturally arises the question of fee; this is given as two, three, or five hundred dollars. The fee is utterly beyond the patient's ability to meet, and he says so finally. Then, if he can only pay what would be regarded as a handsome compensation for some fellow-practitioner whom the distinguished man under consideration knows to be as competent as himself, but who does not enjoy so fine a reputation, the patient is not referred to this competent fellow-practitioner, but is told that he can go to a certain hospital, pay his board, and get the services, valued so highly, for nothing. Now, I am aware that much can be said in favor of such a practice, or in extenuation at least, but

still the struggling practitioner cannot help but feel that he is outraged none the less by the system, and charity is shamefully abused. Yet physicians secretly complain of these things and publicly uphold the very men against whom they feel so aggrieved."

The cry of reform rang out loudly on the question of hospital management. In a very few had the profession any representation in the board of directors, and it was in some of them that the greatest abuse of medical charity could be found. Most of the medical charities in England and this city were founded by medical men, yet they were deemed incompetent to even advise in regard to management, while for their abuse the profession was held accountable.

Reference was then made to the abuse existing in college clinics. "The story is an old one," said the Doctor, "and need not be dwelt upon." In New York 158 doctors held college appointments, and to them the profession in general was asked to look for examples in the observance of that code of ethics which we held up to the admiration of the world.

#### HOW WAS THE ABUSE TO BE REMEDIED?

The Provident Dispensary Plan had not met with the success anticipated. Still the remedy was thought by some to be there. The question, however, arose, how could that reform be applied to college clinics? Reference was made to the plan suggested by Dr. Hanks (see RECORD, May 5, 1877). It was believed that that plan would correct most of the hospital and dispensary abuses. Again, the visitors of "The Association for Improving the Condition of the Poor" could issue tickets for dispensaries to worthy applicants. Again, the Society of St. Vincent de Paul, which had the city divided into districts, would cooperate with our public charities. Of course, the specialists in dispensaries would not like this, because it would limit their material. The clinics and endowed hospitals which were virtually above criticism would not like to be thus hampered. Still that did not detract one whit from the value of the plan as a reformatory measure.

Passing notice of several plans was made but the one most fully dwelt upon was that called "The Home Dispensary Plan." Let those physicians who were interested in a certain class of diseases, or who wished to study up a certain specialty, advertise to the profession in the medical journals, or preferably in the Medical Register, that on certain days and hours they would treat gratuitously, at their own office or any other designated place, the ambulant poor who were affected with certain diseases. Drs. A., B., and C. might treat skin diseases; Drs. D., E., and F. might treat diseases of the eye, etc. They would then become personally responsible for any abuse of their charity, and it was probably safe to assert, that the aforesaid doctors would get all the money they could, even if the fees were insignificantly small. They would study the cases well, and we could rest assured that any deserving patients the profession might send them, would receive good attention.

The first objection presented was that it seemed to be in direct violation of the law in the code which prevented a man from advertising his specialty. Yet wherein was the difference between a man advertising far and wide, not only to the profession, but to the public, that on certain days he would treat all cases of a certain disease at some dispensary, hospital, or college? He was not obliged to put up his sign at the office, as it was put up at the dispensary. Whence would come the drug supply? There were but few patients so poor, but that they could pay a small sum

for medicine. Most apothecaries would prepare prescriptions free for the absolutely poor, provided they had some guaranty that they could get a reasonable number from those who could pay. A doctor could prescribe economically and effectually, if he studied the pockets of his patients.

The plans brought forward were:

1. The Provident Dispensary.
  2. The plan of district visitation under the supervision of a General Board of Charitable Dispensary and Hospital Trustees. The plan proposed by Dr. Hanks.
  3. The connection of hospitals and dispensaries with the Association for the Relief of the Poor.
  4. The appointment of active visitors, to be paid, if necessary, by each board of a dispensary or hospital, whose duty it should be, in conjunction with the house physician, to see that no improper objects received medical charity gratuitously.
  5. The individual effort or concerted action plan on the part of physicians most aggrieved. This simply had for its object the establishment of such an *esprit de corps* in the profession as should prevent any encouragement from the medical profession to the charities thus abused.
  6. The Private or Home Dispensary Plan. Dr. Gibney believed, however, that the first thing to be done in the way of reform was to obtain union of action on the part of medical societies. Let committees be appointed, with chairmen thoroughly versed on the whole question, and able to communicate their thoughts clearly and forcibly. Let these committees crave a hearing before the boards of management of the different dispensaries and hospitals throughout the city in the interest of reform, and let sermons be preached to them until the needed reforms were thoroughly and permanently accomplished.
- The paper was discussed by Drs. Loring, Fox, Porter, Bull, and others.
- A vote of thanks was extended to Dr. Gibney for his paper, and the Association adjourned.

### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from November 11 to November 17, 1877.*

SPORROW, S. A., Major and Surgeon. Relieved from duty in Department of California, and to report to Commanding General Department of the Platte for assignment. S. O. 232, A. G. O., Nov. 13, 1877.

BARNETT, R., 1st Lieut. and Asst. Surgeon. Granted leave of absence for one month, with permission to apply for one month's extension. S. O. 166, Dept. of the Gulf, Nov. 9, 1877.

### Medical Items and News.

TENIA SOLIUM IN A CHILD TWO YEARS OF AGE.—Dr. D. W. Heisberg, of Nebraska City, writes: "According to medical authorities, tenia occurs very infrequently in early life. Dr. J. Lewis Smith, who has had much experience, says in his work on 'Diseases of Children' that he has met but one case only under the age of five years. Others have occurred, but are quite rare. I have now in my possession a specimen of *tenia solium* recently expelled from a child about two years of age. One portion thereof was fifty-nine inches long at the time of expulsion. It was accompanied by forty-nine detached and separate segments. The whole length was estimated to be about eight

feet. This was expelled after administering *spt. terebinthina* with *ol. ricini*. The tenia still remains, however, as segments have since been discharged. I report the case simply from the fact that it occurs so seldom at this youthful age."

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending November 17, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.

POST-MORTEM CESAREAN SECTION.—Dr. Veronden reports that a woman, thirty-five years of age, the mother of several children, and in the sixth month of pregnancy, came under his treatment for syphilis. He gave a very bad prognosis, but her husband begged him, in case the woman should die, to endeavor to save the child, or at least render baptism possible. The doctor soon received notice that the woman had died suddenly during an attack of hæmoptysis. On his arrival at her house, two hours after her death, the fatal heart could still be heard with the stethoscope. The woman was undoubtedly dead, but this could not be determined with *positive* accuracy. Cesarean section was therefore performed, according to the rules of the art, as though the woman still lived. A living child, not yet six months old, was removed. It was carefully carried to the church, baptized, and lived for several hours after the ceremony.—*Norsk. Mag. f. Læv.*, No. 6, 1877.

SANITARY LEGISLATION IN ENGLAND.—The sanitary measures submitted to the English Parliament during the last session were, with one exception, abortive. The one that met with favorable consideration was "The Canal-Boats Act," by which the local government is empowered to make regulations (a) for the registration of canal-boats, including certificate of registration; (b) for the lettering, marking, and number of such boats; (c) for fixing the number, age, and sex of the persons who may be allowed to dwell in a canal-boat, having regard to the cubic space, ventilation, provisions for the separation of the sexes, general healthiness and convenience of accommodation of the boat; (d) for promoting cleanliness in and providing for the habitable condition of canal-boats; (e) and for preventing the spread of infectious disease by canal-boats.

DR. EDWARD SEGUIN'S PRESCRIPTION RECORD has been adopted in France and Italy.

THE CONSUMPTION OF CHAMPAGNE.—Of the sixteen million bottles of champagne that are annually produced in France, only three million are consumed in its native country, the other thirteen million being exported to foreign countries. Over a million bottles are exported annually to North America. In the first half of the year 1876, 604,620 bottles were sent to the city of New York alone. These figures do not by any means represent the entire consumption of champagne in North America, since large quantities are made from California grapes, and not a little is manufactured entirely without the assistance of the juice of the grape.

## Original Lectures.

### TREATMENT OF FRACTURES OF THE SHAFT OF THE FEMUR IN THE ADULT.

CLINICAL LECTURE, DELIVERED IN BELLEVUE HOSPITAL, N. Y.

By FRANK HASTINGS HAMILTON, M.D.

GENTLEMEN:—I have just re-entered upon the duties of my service in this hospital, and I find ten cases of fracture of the shaft of the femur in adults, and under treatment according to a plan which I have adopted for the most part during the past few years. With this number of cases before us, I thought it would be of sufficient interest to devote the entire hour to the consideration of this subject. All these patients with the apparatus upon them have been wearing it since their admission. To some of the patients the apparatus was applied during my previous service.

In order that you may understand precisely the peculiarities of this plan of treatment, it is necessary that I should call your attention to the progress which the treatment of fractures of the thigh has made during the last century. Observe, gentlemen, that I am calling your attention to fractures of the thigh exclusively. I shall also limit myself to the consideration of fracture of the shaft of the femur, not including fracture of the neck or lower third, and I shall limit myself still further by studying the treatment of fracture of the shaft of the femur in the adult.

The treatment of fracture of the thigh in children is exceptional, and differs from that usually adopted in case of the same accident in the adult.

#### TENDENCY TO SHORTENING.

First. I wish to remark that fracture of the shaft of the femur in the adult is almost always oblique. The fracture is usually very oblique, so much so, that it almost never happens that we can set it, in the ordinary sense of the term; that is, we cannot make the fragments set supporting each other. The fracture is so oblique, that unless the fragments are maintained in position by extension and counter-extension, they always overlap each other. This is the law. There are exceptions, of course, as, for example, when fracture occurs in a paralyzed limb, etc.

When the fragments overlap, there will be a projection equal to the entire thickness of the bone. This is illustrated in the specimens you see here. In this specimen the fracture took place about the middle of the shaft, and the overlapping, as you see, is as has already been stated, and the projection is very marked.

The same thing can be observed in another specimen, in which the fracture occurred a little higher up, very near to, but not involving the neck of the bone. In this case there was no extraordinary obliquity, but the fragments overlapped each other fully two inches, the lower fragment riding upwards until it impinged against the neck of the bone.

As a rule, then, there is no such thing as setting a fracture of the shaft of the femur, in the ordinary acceptance of that term. The bone can be placed in position, and held there, perhaps, if sufficiently powerful extension and counter-extension are employed, but it does not set upon itself so as to hold itself.

In this particular instance the plaster-of-Paris dressing was employed, and was applied while the patient

was under the influence of chloroform, and while full extension was made with pulleys. The splint was worn for several successive weeks, and when the patient died, two or three years after, it was found that just such shortening as the condition of the bone would permit had taken place; the lower fragment had ascended until it struck the neck of the bone. Practically, there was no extension or counter-extension in the case.

#### HOW THE TENDENCY TO SHORTENING IS TO BE OVERCOME.

How is the tendency in the fragments to overlap, from the action of the powerful muscles, to be overcome?

Certainly never by setting the bone, as it is called, and then binding it tight with bandages, because you will have cut off all circulation in the limb long before you can bind it sufficiently tight to maintain the proper position of the fragments. This is but plain common sense. No surgeon would dare to attempt to treat fracture of the thigh in that manner. He may put on lateral supports and apply bandages, and the position of the fragments may be in some slight degree maintained by pressing them against each other, but this dressing will not prevent shortening.

How then will you overcome the tendency to shortening?

Until the latter part of the last century all surgeons from the earliest periods employed the long, straight splint. The method was generally to simply pull the limb out to a certain length, and then bind a long, straight splint to the side of the limb and side of the body. The old-fashioned long splint is illustrated by this simple and practical device employed by a surgeon under Stonewall Jackson, that great soldier and good man. It is the simplest and most prompt plan which could be carried into effect in an army constantly upon horseback. Essentially that plan was employed up to the time of Pott, who at the close of the last century wrote an essay, in which he declared that fractures of the thigh all united with great shortening, but that this tendency would be overcome by placing the limb in a flexed position.

This was a new theory, but one which was specious, and which was soon accepted by the English surgeons, a few American surgeons, but never by the French. It soon came to be known as the treatment by the use of the double-inclined plane, although the original idea of Pott was simply to flex the limb, hoping thereby to overcome the action of the muscles. This plan of treatment by the use of the double-inclined plane, or by the flexed position, as it is also called, has its advocates to the present hour.

In England there is, perhaps, no surgeon of eminence who employs it; in France it was never adopted; but in the United States the late Dr. Nathan Smith and Dr. Nathan R. Smith employed it. And Dr. Hodgen, of St. Louis, one of the most distinguished surgeons in the West, still employs this method of treatment. The Drs. Smith employed and Dr. Hodgen employs suspension in connection with it. There are, perhaps, a few other leading surgeons connected with large hospitals who prefer it yet, but almost universally it has been discontinued. These are simple facts, and with here and there rare exceptions, the profession has returned to the use of the straight splint; and I think surgeons have done so because they have found they can make longer and straighter limbs in this position. Let us then return to a consideration of the history and progress of the treatment in the straight position.

[A number of straight splints illustrating the various modifications of the old long splint were exhibited.]

How did surgeons formerly contrive to get hold of the foot in order to make *extension*?

It was always done by means of some form of gaiter, and here you can see some of the varieties which have been employed. They all were intended to get hold of the foot in its circumference, and in as comfortable a way as possible, to afford a means by which extension could be made. But all of them were liable to cause ulceration at some point; sometimes on the instep, sometimes on the top of the heel behind. Ulcers were almost certain to be made if very much weight was employed in making the extension.

As to the *counter-extension*, that was made in essentially the same manner—that is, by some mode of pressing against the tuberosity of the ischium. A variety of methods have been employed, but that which has been most generally used is the perineal band.

But what has been the experience in the use of the perineal band? Every now and then a deep ulcer has been caused by this means of making counter-extension.

We had then two evils to contend with: *first*, the extension apparatus, which was liable to give rise to ulcers upon the top of the foot and heel; and *second*, the counter-extending band, which was liable to give rise to ulcers in the perineum. The liability to make ulcers was so great that the limit of our extension was about ten or fifteen pounds.

#### EXTENSION BY THE AID OF ADHESIVE PLASTER.

At length Dr. Josiah Crosby, of Hanover, N. H., devised the method of making extension by the aid of adhesive plaster applied in strips to the sides of the limb. Broad strips of adhesive plaster were laid along the lateral surfaces of the leg, and secured in place by means of bandages. They take hold upon the skin and nowhere else, and it was soon found that an extension weight of twenty or twenty-two pounds could be used without the least liability of producing ulceration. That was the first great step of progress made in the treatment of these fractures. It gave us a means of making extension which was in every respect satisfactory.

#### MODES OF MAKING COUNTER-EXTENSION.

Still there was need of some mode by which counter-extension could be made without incurring the risk that attended the use of the perineal band. It remained for Dr. Van Ingen, of Schenectady, N. Y., to suggest that, if the foot of the bedstead was raised, we need not use the perineal band.

It is now more than twenty years since I first had my attention drawn to this suggestion, and I did not then believe that it would ever answer as a method of making counter-extension. It will not answer if employed as Dr. Van Ingen recommended, because he raised the foot of the bedstead so high that the patients could not endure the discomfort produced in their heads. But Dr. Moore, of Rochester, took up the suggestion and began to put it into practical application, and it was not long before we became satisfied that it was the method of making counter-extension. It has been many years since I have seen a perineal band in this hospital. We make our counter-extension in every case in adults by simply raising the foot of the bedstead about four inches, and it is sufficient to enable us to apply twenty or twenty-two pounds of extending force, if necessary, without pulling the patient down in bed at all, provided the head and

shoulders are properly supported. This method of making counter-extension certainly never causes ulceration. We have then a means of making extension which does not give rise to any trouble, and the same is true of counter-extension.

In order that we may have the counter-extending force furnished by the entire weight of the body it is necessary that the pillow should support the *head only*, and not the head and shoulders.

#### AMOUNT OF EXTENSION.

I have said that we have a means of making extension which permits us to use twenty or twenty-two pounds weight, and that that is the full extent to which it should be carried.

Why may we not make greater extension?

Because the ligaments of the knee-joint will not permit of greater extension without becoming painful.

If we stand in a position in which the knees are thrown back to their full extent, they soon become painful, and the position cannot be maintained without great suffering.

We usually stand with the knees bent at an angle of one or two degrees, and if straightened more they become painful.

Some patients will bear fifteen, some twenty, and some twenty-two pounds extension, which is the extreme amount that should be employed. By no means put on such an amount of extension as causes the patient pain.

#### PLASTER-OF-PARIS IN THE TREATMENT OF FRACTURE OF THE THIGH.

A few years ago, at the suggestion of German surgeons, who have done so much good and praiseworthy work, American surgeons began to use plaster-of-Paris in the treatment of fractures of the femur. In adopting that plan of treatment, they went a step backward instead of forward, for they adopted a method by which they could not secure any degree of extension and counter-extension, as any one can satisfy himself by watching a case throughout its treatment. It is easy of demonstration that it does not afford any extension and counter-extension. If the plaster is put on so that pressure is made on the perineum, it will cause ulceration. I have seen a case in which ulceration extended through the perineum, and up the back six or eight inches, and as deep as my hand. If you do not use the perineum to make pressure against, you must use the side of the thigh.

What kind of a surface does the thigh furnish? It is an oblique surface; there is a gradual decline from the hip to the knee, and inasmuch as the plaster will loosen within four or five days, so that you can run your hand in between it and the surface of the limb, there is no counter-extension at all; not the slightest.

The entire foot and limb may be enclosed in plaster as snug as you please, but you have no counter-extension; not a particle. While the plaster was being used in this hospital, I saw more shortening than I ever saw before in my life, and I saw two or three deaths, occasioned by the use of the plaster-of-Paris dressing.

These cases have been carefully recorded in the 5th edition of my work on Fractures.

I think we have gone several steps backwards when we use the plaster-of-Paris dressing, and I am happy to say that it is almost abolished. At the present time there is scarcely one of my colleagues in this hospital who employs it in the treatment of fractures of the thigh; there may be one, but I am sure you will not use it more than once or twice in country practice.

## TREATMENT OF FRACTURE OF THE FEMUR BY MEANS OF BUCK'S EXTENSION APPARATUS.

We come next to the treatment of fracture of the thigh by means of what is known as "Buck's Extension Apparatus."

Let us look at this patient and see what kind of an apparel he is wearing.

In this particular case, as you see, no side splints have been applied to the thigh. Ordinarily they are employed. Nor is the apparatus complete in other respects, but extension and counter-extension are being made, and so the case is progressing very favorably.

The dressing in this case shows you only how extension and counter-extension should be made.

I wish to say, in connection with this case, that so long as I have treated fractures—now more than forty years—I have never met with a case in my own practice in which the fragments did not finally unite.

I have seen very many cases of non-united fracture, with other surgeons, but I do not wish to say that it has been because of improper treatment on their part; it has simply so happened that I have not had that result to deal with in my own practice.

In this case you see illustrated a suggestion made by Esmarch for the purpose of preventing rotation. I think we have a much simpler way of accomplishing the same thing; but this little device does accomplish the thing desired, and prevent rotation of the limb outwards.

The apparel, when complete, as I usually employ it, is generally known as Buck's extension. But Dr. Buck was not the first to employ the adhesive plaster, or to suggest raising the foot of the bed for the purpose of making counter-extension, and these are the most essential features of the treatment. So it is with other parts of the apparatus. We are indebted to Dr. Buck for a great deal in the treatment of fractures, but this apparatus has been so long employed in this country and so much modified that it may with more propriety be called American. In this case the apparatus is complete, and let us see what we have. *First*, we have two broad strips of adhesive plaster reaching from the knee to a few inches below the foot, and secured to the sides of the limb by means of a roller bandage. A piece of board is attached to the lower ends of the strips of plaster, and from the centre of the board a cord passes over a pulley fastened to the foot of the bedstead. In some of these cases you will notice that we have two pulleys, and in others only one.

Originally, a simple straight piece of board, having a mortise in it, as you see, and carrying a pulley, was secured in the upright position to the foot of the bedstead. The upright seen here is iron and can be adjusted and removed with ease; it is an improvement; that is, it is somewhat more convenient than the original wooden board.

The piece of board to which the adhesive straps are attached must be of sufficient length, so that when extension is made they will not impinge upon the malleoli.

The strips of adhesive plaster need not go above the knee.

Then as to the counter-extension. We have, as you see, no perineal band. We have simply raised the foot of the bedstead about four inches, and have seen that the patient rests his head, *not his shoulders*, upon a pillow. We next apply four short side-splints to the thigh; three will not answer; it is necessary to have four independent side-splints, which nearly encircle the limb. We are employing here splints constructed of felt, which is made of several thicknesses

of cotton cloth. This material is one of the best that can be employed for this particular purpose as it is easily worked, is sufficiently flexible, and at the same time possesses sufficient firmness.

These side-splints are secured in position simply by encircling the limb with four or five fillets and tying them with a convenient knot. In this manner the fragments are kept in proper coaptation, and the splints can be easily removed to afford an opportunity for inspecting the limb.

In addition, you see fastened to the side of the limb and to the side of the body a long splint, about four and one-half inches in width extending nearly to the axilla, and having at the lower end a broad cross-bar to prevent its tipping.

What is the use of all this? *First*, it prevents eversion of the limb.

*Second*, and most important, it keeps the limb and body in a direct line.

If the fracture is pretty high up, or even in the middle third of the femur, I regard the long side-splint as the most essential part of the apparatus in securing the broken femur in an absolutely straight line.

In the case before you the fracture is nine weeks old; union is not yet perfect, but the limb is perfectly straight.

This is the model dressing for fracture of the thigh occurring in adult life, and in its present improved condition is the splint employed by the larger portion of the surgeons throughout this city.

When plaster-of-Paris was first introduced as a means to be employed in the treatment of fractures, the idea was that the splint could be kept on until the treatment was completed.

I have treated a great many cases myself in that manner, and I know what I say. It was found that scarcely ever more than two or three weeks elapsed before it became necessary to cut the splint open, remove a piece, and then bring it together and secure it with a bandage, or else remove it altogether and adjust a new one.

When a plaster splint is cut open and a piece removed, it will never properly fit the limb again, so that it becomes an almost absolute necessity to expend a prodigious amount of labor in removing the dressing entirely every two or three weeks and applying another new splint.

## SHORTENING IN FRACTURE OF THE FEMUR.

In nearly all these cases treated by extension and counter-extension there is more or less shortening. That is the rule. In this case the amount of shortening is three-sixteenths of an inch. Formerly the average amount of shortening varied from three-quarters to one inch; now it is usually one-half inch, or less.

Here is a case, gentlemen, in which the plaster splint has been applied for purposes of illustration.

In order to secure extension even temporarily, the plaster splint must be carried over the foot, and then it must be extended up over the limb and through the perineum; then it is carried around the pelvis so as to embrace it completely.

If this splint remains on a week it will be loose—indeed, it is so loose now, and it was applied this morning, that the band can be slipped in between it and the skin around the pelvis and perineum, and you can see that it affords nothing in the way of counter-extension.

This is the ordinary method of using plaster-of-Paris in the treatment of fracture of the thigh.

[Several cases were exhibited and brief allusion made to the peculiarities in each.]

## Original Communications.

### ON THE USE OF CERTAIN TRITURATIONS.\*

By HENRY G. PIFFARD, M.D.,

NEW YORK.

THE high estimation in which triturations are held by homeopaths induced the writer some time since to carefully consider the relative advantages and disadvantages which they possess, in comparison with other pharmaceutical preparations in which the medicine is dispensed in a solid form. In the U. S. Pharmacopœia the number of triturations is limited, and includes only the Pulvis aloës et canellæ, the Pulv. aromatics, the Pulvis jalapæ comp., the Pulv. rhei comp., the Pulv. ipecacuanliæ comp., and Hydrargyrum cum cretâ. Concerning the first four, the Pharmacopœia directs that their ingredients shall be rubbed "together until they are thoroughly mixed." Of the Pulv. ipecac. co., or Dover's powder, it says that the ingredients shall be rubbed "together into a very fine powder." Lastly, the mercury and chalk are to be rubbed "together until the globules cease to be visible." In the former instances the effort is simply to obtain powders of uniform appearance, but in the last two undoubtedly the intention is to obtain the drugs in a state of minute subdivision, and these alone may properly be considered as falling under the designation of triturations. The homeopaths, on the other hand, prepare a considerable number of medicinal substances in this manner, and it becomes a question of interest whether or not it would be advantageous to extend our own list in this direction.

The homeopaths prepare their triturations by two different formulæ, known respectively as the *decimal* and *centesimal* scales. In the first case one part of the drug is triturated with nine parts of milk-sugar, and the result designated 1st decimal, or 1<sup>x</sup>. In the second case, one part of the drug is rubbed with ninety-nine of sugar and is called 1st centesimal, or 1<sup>o</sup>. One part of one of these mixtures is again triturated with nine or ninety-nine of sugar, and the result designated as 2<sup>o</sup> or 2<sup>x</sup> as the case may be, and so on *ad infinitum*. In each case the process of trituration is carried on for an hour, and to a considerable extent is effected by the aid of suitable machinery, the object being to subdivide the drug as thoroughly as possible. As many of these triturations contain, in a convenient bulk, the doses that we commonly prescribe, they at once become eligible preparations for our use, provided they are as convenient to dispense and as uniform and certain in their effects as the preparations that we ordinarily employ. If they excel in these respects, they should certainly be brought into more general use, as it is our duty and privilege, as regular physicians, to avail ourselves of every therapeutical agent and of every pharmaceutical process that may be better than those heretofore employed. In order to settle in our own mind the relative value of triturations, we have, during the past year, carefully investigated a few of them, more particularly those of mercury, arsenic, and iron.

The first chosen for examination was the 1<sup>x</sup> trituration of *mercurius vivus*, and it was compared very naturally with our own analogous preparation, the *hydrarg. c. cretâ*. Examined under the microscope the mercury in the former was found to be in a state of extremely minute subdivision, the majority of the separate globules being smaller than red blood-corpuscles,

and many of them so small as to be endowed with Brunonian movement.

Five samples of *hydrarg. c. cretâ*, obtained from Broadway drug stores, were then examined. These were found to vary greatly in their gross appearances, and likewise under the microscope. In some there appeared to be a notably larger proportion of mercury than in others, and in all of them the metallic globules were very much larger in size (average) than those in the *merc. viv.*

Now when we administer mercury for its specific effect upon the blood or upon particular organs, the first essential is that it shall be absorbed. If the drug is in solution there is of course little difficulty about the matter, but if given in a solid form, it must either be capable of solution by the fluids of the stomach, or else its particles must be sufficiently minute to permit of their direct absorption as solids. The fact of the absorption of solids, at one time deemed impossible, has now been so thoroughly demonstrated, and especially as regards mercury, that we are prepared to understand how minute subdivision will facilitate absorption, when larger particles would pass the bowels without effect, or simply produce local effects, varying with the nature of the drug employed. We should therefore expect that, a given quantity of drug being used, the promptness of its specific effects would vary inversely with the size of the particles of which it is composed. If we submit this rational conclusion to the test of clinical experience in the cases of *hydrarg. c. cretâ* and *mercur. viv.* we will find it easily verifiable. The latter, given in doses containing the same amount of mercury as the former, will produce the more prompt and decided effects.

Turning from metallic mercury to its salts, we find an inviting field for exploration. The mercurous preparations are almost invariably given in the solid state, while the mercuric are administered both in the solid form and in solution.

We are all of us aware that a single grain of calomel well rubbed up with sugar and given in, say, twenty divided but frequently repeated doses, will often produce the specific effects of the drug, while a single dose of twenty grains will as frequently fail to do so. Passing calomel, then, we come to another mercurous preparation, namely the protoiodide. This salt, in its condition of ordinary medicinal purity, was found, upon microscopical examination, to consist of comparatively large-sized masses composed of apparently smaller granules. Moderate pressure on the covering glass was sufficient to disintegrate these masses and to resolve them into much smaller particles, not exhibiting crystalline structure, and averaging about the size of red blood-corpuscles, or a little less. A gelatine-coated protoiodide pill was found to contain the drug in the same fine granular condition. Sugar-coated pills of French and American manufacture were also examined, and the mercury found to be in quite small particles. In all of these specimens the drug was in a very minute state of subdivision, and the greater part of it doubtless capable of direct absorption without previous solution. This is of importance when we consider that this salt is but sparingly soluble.

The first decimal (1<sup>x</sup>) milk-sugar trituration of the protoiodide was next examined. In this the salt appeared to the naked eye to be very uniformly distributed throughout the powder, and upon microscopical examination was found to consist of extremely minute particles, of decidedly smaller size than in the previously examined specimens. It is to be expected, therefore, that the protoiodide trituration will prove, *ceteris paribus*, more active than the pill, and such we have found it.

\* Read before the N. Y. Academy of Medicine, Nov. 1, 1877.

Turning now to the mercuric preparations, we find the bichloride and biniodide most in use. For obvious reasons, triturations of the former were not examined microscopically. Gelatine- and sugar-coated pills of the biniodide, however, were carefully investigated. In the gelatine-coated pills we found the salt displayed as beautifully perfect crystals of varying size. In the sugar-coated preparations the drug was in small granular masses, held together by some not very soluble substance. In the first centesimal (1<sup>st</sup>) trituration the biniodide was apparently well distributed through the powder, and upon examination was found in particles of very much smaller average size than in any of the other preparations. The biniodide of mercury is exceedingly insoluble, and there can be no question but that its absorption is therefore very much facilitated by minute subdivision. It is moreover a powerful irritant, and one would naturally expect that particles too large for direct absorption, or slow of solution, would be apt to produce more or less gastric distress before they are finally disposed of. That the iodides of mercury frequently produce gastralgia and diarrhoea is well known, and personally we believe that this is due to the local irritation produced by them, and not to any elective action of the drug. Since we have used the triturations, however, in preference to the ordinary pills, patients more rarely complain of disagreeable sensations. We have further been enabled to materially reduce the size of the dose, in order to obtain the desired effect. In other words, a larger proportion of the drug is utilized for specific purposes, while but a small amount remains to give rise to local irritation.

Besides those already mentioned, we have employed with equal satisfaction triturations of arsenious acid, the iodide and bromide of arsenic, ferrum redactum, aloes, sulphide of calcium, iodide of sulphur, and others, and are prepared to assert, without hesitation, that they are more prompt and reliable than pills, as ordinarily prepared, and that in many cases the medicinal effect being the same, their action is milder and less disagreeable to the patient.

Besides mineral and metallic, many vegetable substances might with advantage be kept in this form, as aconitine, atropine, digitaline, picrotoxin, strychnine, etc., in the 2<sup>d</sup>, and morphine, codeine, elaterium, pilocarpine, etc., in the 1<sup>st</sup> trituration. In this connection the greater facility for accurate dosage is not to be overlooked.

At present, if but a few doses of one of the more powerful alkaloids is required, a large number of doses must be prescribed in order to secure any approach to accuracy in dispensing. With triturations this difficulty is obviated. They also afford convenient means for the extemporaneous preparation of hypodermic solutions of atropine, strychnine, etc., at times when the services of an apothecary cannot be readily obtained. To the city practitioner, at night, a few triturations carried in a pocket-case would often enable him to meet emergencies without the hour or half hour's delay in having a prescription prepared. To the country practitioner they are invaluable.

In conclusion, while willing to give due credit to the homeopaths for their development (though not for the invention) of this class of pharmaceutical preparations, we see no good reason why they should any longer enjoy the monopoly of their use.

The triturations referred to above were made by Boericke & Tufel, and some of them I have had compressed into convenient doses by Wyeth & Bro., of Philadelphia.

## RETENTION OF PLACENTA FROM ATMOSPHERIC PRESSURE.

REPORTED BY W. E. FOREST, M.D.,

RESIDENT PHYSICIAN, LYING-IN ASYLUM.

Dr. A. LUTON has communicated to the Medical Society of Reims a case of retention of the placenta due to atmospheric pressure. Recently a case occurred in my practice which, owing to a peculiar condition of the abdomen of the mother, offered unusual facility for investigating the truth of his theory.

Jane K., age thirty seven; mother of four children; labors usually easy; taken in labor at 3 A.M., Oct. 26th. Made an examination at 6 A.M. Os dilated to the size of a silver dollar. Membranes unruptured. Head presenting in the R. O. P. position.

The labor progressed slowly through the day.

At 5½ P.M. found the head in R. O. P. position, and making no progress. Os fully dilated and head well advanced. Administered chloroform, Dr. E. L. Partridge assisting, and delivered with the forceps, the head rotating from R. O. P. position to R. O. A.

After the delivery of the child I examined the abdomen of the mother and found that during the labor the recti muscles had separated in the median line for a distance of five inches, and extending from the ensiform cartilage to the pubes, so that we had, as it were, a door opening into the abdominal cavity, the abdomen being covered only by loose integument.

Pressing the loose folds of integument before my hand, I found that I could pass the hand down behind the uterus into the pelvis so as to take the body of the uterus between the hands, and could distinctly distinguish the bundles of muscular fibres making up the outer muscular layer of the uterus. The abdominal aorta could be compressed between the fingers, and, indeed, almost every abdominal organ could be felt *in situ*. This condition afforded an excellent opportunity for examining the uterus during the expulsion of the placenta. Fifteen minutes after the child was born I made traction upon the cord and firm pressure upon the fundus uteri, after Credé's method, to assist in the expulsion of the placenta. The uterus was at this time quite firmly contracted.

The placenta resisted all attempts to extract it, and I could distinctly feel the anterior wall of the uterus sink in at every pull made upon the cord. Either the placenta was adherent to the wall of the uterus, or possibly the placenta, with the cord attached to its centre, was acting as a "sucker," similar to the toy made of a round piece of wet leather with a string attached to its centre, which small boys amuse themselves with.

In either case there was danger of causing inversion of the uterus, if traction was made upon the cord. I requested Dr. Partridge to place his hand upon the depressed wall of the uterus (the uterus was separated from his hand only by the thickness of the integument). Then, holding the cord firmly in one hand, I passed the other up to the os uteri, and found the centre of the placenta presenting at the external os, the placenta being in the shape of an inverted umbrella. I inserted two fingers past the anterior edge of the placenta, without making any traction. As I did this, Dr. Partridge exclaimed that the sunken wall of the uterus had resumed its natural shape, and an instant later the placenta, almost by its own weight, came down into the vagina, and was delivered.

This manœuvre of passing the fingers between the edge of the placenta and the uterine wall, allowed the

air to enter the uterus and thus relieved the atmospheric pressure upon the fetal surface of the placenta.

The care with which this experiment was conducted, and the exceptional opportunity afforded for making an accurate examination of the uterus, goes far to make this case almost a demonstration of the theory that retention of the placenta may sometimes be due to atmospheric pressure.

This cause for retention of the placenta I have never seen mentioned in any obstetrical work; and yet I am inclined to think it a frequent cause. Nearly every obstetrician can recall cases where, after strong traction on the cord has failed to bring down the placenta, the hooking the finger over the edge of the placenta has brought it down almost without the expenditure of force. The common explanation of this condition is that it is necessary to "unbutton the placenta."

Now, this plausible illustration misleads one as to the real state of the case. The soft, dilatable os uteri resembles not at all the slit-like opening of a button-hole; nor does the compressible cone-shaped placenta (cone-shaped when traction is made upon the cord) resemble a button. We should expect, too, that the os uteri, which has just given passage to the head of the child, measuring  $3\frac{1}{2}$  inches in its shortest diameter, would not obstruct seriously the passage of the placenta, which I have found can usually be drawn through a ring  $2\frac{1}{2}$  inches in diameter. The true explanation may be that in these cases of retention of the placenta, the uterine sinuses do not pour out sufficient blood to fill up the uterus behind the placenta, and hence atmospheric pressure upon the fetal surface of the placenta prevents its expulsion or extraction.

No. 170 SPRING STREET, NEW YORK.

## Reports of Hospitals.

### THE TREATMENT OF ACUTE RHEUMATISM IN THE HOSPITALS OF CHICAGO.

#### COOK COUNTY HOSPITAL.

In this hospital, during the rheumatic season last spring, there were treated quite a variety of cases of acute rheumatism. The treatment, except in the cases with complications, was generally that with salicylic acid. The acid was rarely, if at all, given in an uncombined state. One combination was that with the liquor of the acetate of ammonia, glycerine and water; with each 15 grains of the acid there being one drachm of glycerine and twice as much of the liquor. The combination prescribed by Prof. Lyman was made with a solution of the bicarbonate of soda—this drug being added until a perfect solution is made. Each dose, representing 10 grs. of the acid, contained also 4 grs. of citric acid. The usual dose was 10 grs., and this was repeated every hour in a few cases; the more common interval, however, was 2, 3, or 4 hours. Occasionally a few doses of 20 grs. each were administered, and in a few cases 5 grs., and even less, was given at each dose. There was little or no complaint of irritation of the stomach from the medicine. There were eighteen uncomplicated cases for which the salicylic acid was the chief treatment—in a few of these it was acid the sole treatment. In sixteen of these cases the average time of the attack before this treatment was begun was  $2\frac{1}{2}$  days. (Of course it was begun as soon as the cases were admitted.) Of the eighteen cases the average time in hospital after the acid was begun was  $11\frac{1}{2}$  days, and the average length of the attack in these

cases was 22 days  $5\frac{1}{2}$  hours. The time from the beginning of the administration of the acid to the appearance of a marked abatement in the articular inflammation, is recorded in only nine cases, and the average was 2 days 18 $\frac{1}{2}$  hours. The average quantity of the acid given each patient each day was about 85 grains.

The following table expresses more in detail the facts in each case. It is made from the records:

Cases.	Length of sickness before treatment was begun.	Time after onset of attack in hospital.	Dose and intervals.	Time of use of the medicine before.	Whole length of sickness.	Result.
Man, 45	1	8	10 grs., 4 times daily	2	9	Cured.
Man, 38	4	6	5 grs., every hour	2	10	Cured.
Woman, 22	10	21	10 grs., every 4 hours	2	31	Complicated with abscess.
Man, 18	7	30	10 grs., 3 times daily	3	37	Complicated with abscess.
Man, 29	3	19	10 grs., every 2 hours	3	22	Cured.
Woman, 27	11	30	10 grs., every 2 hours	3	41	Cured.
Man, 43	11	8	4 times daily	8	19	Unimproved only.
Man, 27	11	8	2½ grs., every 3 hours	8	19	Cured.
Man, 41	11	20	10 grs., 3 times daily	1	22	Cured.
Man, 35	21	12	20 grs., every 3 hours	1	32	Relapsed 2 days after admission, relieved in 5 days.
Woman, 42	7	37	10 grs., 4 times daily	1	44	Relapsed 2 days after admission, relieved in 5 days.
Man, 24	7	6	10 grs., 2 times daily	2	13	Heart complication.
Man, 28	6	10	10 grs., 3 times daily	2	16	Heart complication.
Man, 24	6	40	10 grs., 3 times daily	3	46	Heart complication.
Man, 19	6	27	10 grs., 4 times daily	3	33	Heart complication.
Man, 35	6	6	10 grs., 3 times daily	4	10	Heart complication.
Man, 33	6	6	10 grs., 3 times daily	4	10	Heart complication.
Man, 33	4	8	10 grs., 3 times daily	4	8	Heart complication.
Man, 35	4	8	10 grs., 3 times daily	4	8	Heart complication.
Man, 31	10	9	10 grs., 3 times daily	4	14	Heart complication.

It is highly probable that in the hurry of hospital work the exact date of an abatement in the severity of the symptoms in some of these cases may not have been recorded. The judgment of the hospital attendants is that such abatement occurs usually in a much shorter time than that stated in the table as the average.

#### ST. JOSEPH'S HOSPITAL.

Here there were admitted during the spring and early summer—in the service of Prof. C. T. Parkes—five cases of acute rheumatism. Four received the salicylic acid treatment. The medicine was administered in a pure state, and was found to disagree with the stomach, after a few doses had been given, in two cases. In these it was soon discontinued and an alkaline treatment with opium given in its stead. In two cases a very marked improvement—almost a cure—was manifested in two and three days respectively, by doses of 10 grs. every 2 hours and 5 grs. every 3 hours respectively. In these cases the acid was well borne by the stomach. In both the cases in which the acid was found to disagree, the doses were of 10 gr. each, and were repeated every 2 hours.

#### ST. LUKE'S HOSPITAL.

Dr. M. O. Heydock, who is in charge of the medical wards of this hospital, has not made any careful test of the effects of the salicylic acid in acute rheumatism, i.e., unaccompanied by other medication. He has ad-

ministered the acid to many patients, but has generally combined with it not only a thorough alkaline treatment, but has often applied blisters as well. The last-mentioned measure of treatment has been unusually successful in the hands of this practitioner, not only in the pains and inflammation of rheumatism, but in many other painful and neuralgic affections. Dr. H. has not lost confidence in the old treatment of rheumatism with guaiacum and colchicum, and iodide of potassium—with a liberal administration of opium for the quieting of pain.

#### MERCY HOSPITAL.

In this hospital it has been the practice for many months to administer salicylic acid to cases of acute rheumatism, especially if, when admitted, they are found to have a high fever and much pain. The average dose of the acid is 10 grs., but 15 gr. doses have been frequently given. The interval between doses is longer than is usual in the other hospitals of the city, four hours being the average interval. Only occasionally has the medicine been given more frequently. The acid is usually combined with some alkali, a favorite being borax, about 10 grs. being combined with each dose of the salicylic acid.

Within forty-eight hours after the acid treatment is begun, usually some other medicament is added, which would make it perhaps difficult to say just what the effect of the acid might be. For example, Prof. Merriam usually administers to his patients large doses of bicarbonate of potassium, with, perhaps, iodide of potassium and colchicum in liberal quantities, while the salicylic acid is being taken. Prof. Davis with his patients is likely to add to the salicylic acid iodide of potassium, tincture of cimicifuga, and the tincture or the fluid extract of stramonium. The two last-named drugs have been peculiarly useful in his hands.

It is the opinion of the staff of this hospital that salicylic acid is capable, in the doses given, of lessening fever and pain and tenderness in acute rheumatism in the majority of cases, and that within two days after its use is begun; but their opinion is as clear and positive that it is incapable of such success in every case.

There is no complaint that the acid disagrees with the stomach when given in the combinations here used. One form in which the acid is administered—not mentioned above—is in an uncombined state mixed with the extract of malt, several drachms of the extract being used to disguise each dose of acid. This expedient is very highly spoken of.

In private practice in Chicago the powdered salicylate of soda is coming into use, and is greatly liked because of its blandness to the tongue and stomach, but it has not found its way into the hospitals to any extent as yet.

CHICAGO, Nov. 2, 1877.

### Progress of Medical Science.

**CARBOLIZED CATGUT LIGATURES AND THEIR EFFECT UPON THE HUMAN ARTERIES.**—At a recent meeting of the Clinical Society of London, Mr. Bryant instanced some cases from his own practice, which, with drawings and preparations, are calculated to aid in solving the question whether catgut is an appliance that should merit general use. His first preparation was taken from a patient in Guy's Hospital, who had been suffering from aneurism of the right femoral and ulcerative endocarditis. A catgut ligature was applied to the external iliac artery, but death occurred from the heart affection fourteen hours subsequently. The

inner and middle coats of the artery were found, on post-mortem examination, to be completely divided by the ligature, and the external coat partly. Below and above the ligature were clots, and the catgut was intact. The second preparation was taken from the right common carotid, to which a ligature had been applied twelve days before death. In this case the artery had been completely severed. There was a clot above and below the point of separation, but it was not firmly adherent. The ligature had disappeared. In the third preparation the right subclavian had been tied with catgut thirteen days before death. The man had died of lung trouble. In this case there was a firm clot in the vessel for half an inch above, and for the same distance below the ligature. All the coats had been divided and afterwards repaired; the knot of the ligature was all that remained. In the fourth preparation the common femoral had been tied nineteen days before death. Death ensued from gangrene. All the coats of the artery had been divided and repaired, and good clots existed above and below the ligature, the knot of which, with perhaps some of its loop, remained. In all these cases the inner and middle coats of the vessels had been probably divided at the time of operation, as would be done by any permanent ligature, the external coat afterwards by an ulcerative process, though in the first case this was partially accomplished in fourteen hours. He has operated in a number of other cases, and has reached the conclusion that the ligature at first divided the middle and inner coats, and then excited ulcerative action in the external coat. "If, therefore," said Mr. Bryant, "I cannot endorse what the distinguished introducer of the catgut ligature claimed for it in 1869," that by applying a ligature of animal tissue antiseptically upon an artery, whether tightly or gently, we virtually surround it with a ring of living tissue, and strengthen the vessel where we obstruct it, "yet I may express my belief that as the loop of the catgut ligature dissolves within an uncertain period, and there is not of necessity any sloughing or ulceration of the whole coat of the constricted artery, as must ensue where a more permanent material is employed, we have in the carbolized catgut the best ligature at our disposal." Mr. Maunder stated that in his personal experience the use of catgut in the continuity of vessels had been attended with success, but he knew that with others the case had been different. As to the matter of accidents following the catgut, he stated that it had frequently dissolved in twenty-four hours, and fatal hemorrhage had taken place. He was not in favor of this ligature in the continuity of vessels and should no longer employ it. Mr. Barwell stated that he had employed the ligature in five cases, and no accident had resulted in any. It was advisable not to draw the ligature too tight, for the more tightly it was drawn, the more rapidly it was dissolved.

**SYME'S AMPUTATION AS THE MOST ADVANTAGEOUS AT THE ANKLE-JOINT.**—Dr. Hudson, whose name has long been associated with various mechanical appliances for supplying artificial supports, to relieve deformities, or compensate for losses of limbs, has written an article which will supply much useful information to those who may be in doubt as to the special desirability of this or that operation at the ankle-joint. The writer thinks that the results of Syme's operation, as performed by scientific and expert surgeons during the past twenty-five years, have given conclusive evidence of its special advantages to the patient, and demonstrates its superiority over every other amputation of the foot or leg. It is thought to be the "least disabling,

found with a moderate degree of contraction, usually the least incapacitating, and with scientific prothetic apparatus, the patient scarcely realizes any loss of limb. The end of the stump is painless and an enduring basis of support, reliable for any degree of pressure and service, and equivalent in condition and functions to the heel of the unamputated foot." The writer also adds that the merits of a well-performed Syme's amputation cannot be exaggerated, and claims that he is able to sustain his position by tabulated records of two hundred cases, of which he has notes. It is thought that no amputation of the leg or foot should be substituted for the Syme, except that of Lisfranc. No improvement on the Syme method can be made by section of the cancellated structure of the ends of the tibia, or of the calcaneum. Pirigoff's method is preferable to leg amputation, but when any considerable part of the calcaneum has been amexed, the form has been uncouth, and the basis of support poor and painful. Some have resulted in a false joint and retraction of the appended part; others in necrosis of the tibia above the amexed portion of the os calcis. The increased length of stump in such cases should not be urged as an advantage *to the poor man*. If in his case the bucket arrangement alone is available, an elastic wool felt pad half or five-eighths of an inch thick in the bucket will be amply sufficient to offset any advantages afforded by the appended calcaneum. In fine, a comparison between the Pirigoff, Chopart, Quimby's so-called modification, and a leg amputation with periosteal flaps, the tibio-tarsal, or Syme's, is thought to be *the most useful and worthy*.—*Louisville Med. News*, Nov. 3, 1877.

#### INJURY RESULTING FROM ELECTRICAL TREATMENT.

—Dr. Lincoln reports some interesting cases in which the application of electricity gave rise to unpleasant consequences. In a case of rheumatic arthritis, the usual galvanic treatment at first relieved the pain, and imparted a sense of vigor to the body. After the first two or three weeks, however, the benefit became less marked, and soon an acute attack, or exacerbation of the disease set in, which Dr. Lincoln thinks might reasonably be attributed to the treatment. In a case of spinal exhaustion, galvanization induced restlessness and sleeplessness, from which the patient had never suffered previously, and which continued to trouble him as long as he received electrical treatment, without being balanced by any good results whatever. A case of muscular rheumatism was very rapidly improved, but this improvement was followed by severe dyspepsia, and great prostration, cured in a short time by change of air. A lady suffering from locomotor ataxia received direct relief from each application. This relief lasted twenty-four hours, but was followed the next day by an exaggeration of the symptoms; she was worse at the end than at the beginning of the treatment. A case of muscular pain and weakness of the legs was always rendered worse the day after the application of the electricity. The Doctor then mentions some other undesirable effects, which were, however, transitory in their nature. In conclusion he says: "As far as I am able to judge, the harm that may be done by electricity mostly arises from over-stimulation, that is, exhaustion of the spinal, or ganglionic systems."—*Boston Medical and Surgical Jour.*, October 25.

**CONGENITAL PHIMOSIS.**—Foremost amongst the unpleasant effects of congenital phimosis, Dr. Pooley places incontinence of urine. Nocturnal enuresis in boys he regards as being almost always due to this cause. An extreme degree of preputial contraction is not necessary to produce this result, for it is frequently

complicated by adhesions between the foreskin and glands, and by the presence of hardened smegma behind the corona. The exact connection between the cause and effect is not explained, but reflex action is suggested. The irritation of the secretion and urine retained behind the foreskin is often sufficient to give rise to a balanitis, with such a copious discharge of pus as to simulate clap. This inflammation, Prof. Pooley says, may extend down the urethra to the bladder, and may give rise to a veritable cystitis, presenting all the symptoms of stone in the bladder, and only distinguishable from that affection by sounding. The remedy is circumcision, an operation which, in his experience, is always followed by good results. In operating he recommends the use of the clamp in removing the tegumentary layer of the prepuce, then turning back the mucus layer and attaching it to the cut edge of the skin by numerous fine black silk sutures. This inner layer may require division on a director, and if there are any bands of adhesion they should be broken up. The wound should be dressed with a strip of oiled lint, and a cold-water bandage. In urinating, the child should lean well forward, to prevent the dribbling of the urine over the wound.—*A Series of American Clinical Lectures*, No. 21.

**OPERATIVE TREATMENT OF INTERNAL PILES.**—In a paper published in the *Edinburgh Medical Journal* for June, 1877, Mr. Annandale discusses the comparative advantage of the clamp and cautery, and the ligature in the operation for internal piles. Mr. Annandale prefers the clamp and cautery, and states the advantages of this method over the use of the ligature, as follows:

1. By means of the clamp and cautery the piles are at once removed, and do not remain in the rectum as dead and putrid masses.
2. The irritation and pain are not so severe or so prolonged as in the operation by ligature.
3. The patient's confinement to bed and to the house is much shorter.
4. The resulting sores heal more quickly, and are attended with less risk of suppuration, and its attendant local and general dangers.

**FRACTURE AT THE SUPERIOR EPIPHYSIS OF THE HUMERUS.**—In the *New York Medical Journal* for November, Dr. Richmond reports a case of fracture of the humerus at the superior epiphyseal junction, treated according to the method recommended by Dr. E. M. Moore, of Rochester. Dr. Moore's plan is "to carry the arm forward and upward while moderately extended; the upper fragment rolls upward in the glenoid cavity until arrested by the capsular ligament, when the lower fragment slips into its normal relation with the former. The arm may be brought down to the side in a state of moderate extension, and easily held in position by a Livinburn extension splint." Dr. Richmond's case occurred in a young man, nineteen years old, who fell backward a distance of six feet. In performing the manipulations, a slight or "muffled" crepitus was elicited. After reduction there was no tendency of the fragments to become displaced. An outside splint was used, and a strip of adhesive plaster applied to the inside of the arm, carried below elbow, around lower extremity of splint, and thence through a hole in the splint to the outside of the arm. This gave the extension. Counter-extension was made by means of an axillary band fastened to the upper extremity of splint, which extended somewhat above the shoulder. The whole was then secured by a bandage. The treatment lasted five weeks, and the result was *perfect*.

## PROFESSIONAL SECRETS IN COURT.

SINCE the editorial of last week was written there has been more discussion in the secular papers concerning the revealing of professional secrets in court. The subject is such a broad one, and admits of being viewed in so many lights, we are not surprised that it has been made the most of by our daily contemporaries. A great deal that has been said upon the strictly professional aspects of the case has been absurd, but nevertheless the general sentiment which has prevailed that professional secrets should never be divulged is eminently proper. As we have remarked on a previous occasion, there has never been any doubt among physicians regarding this point. As a matter of abstract principle it has been defended on several occasions in defiance of the rulings of courts, and medical men have been accordingly sent to prison rather than violate their professional obligations to their patients, or act contrary to the dictates of their consciences. It is one of the maxims which is early inculcated in the minds of every properly qualified medical man, and is universally conceded to be one of the very necessary reasons why the Hippocratic oath should be administered to every graduate. Under these circumstances, to receive a rebuke from the secular press for ostensibly violating this most sacred of all obligations is, if at all merited, in the highest degree humiliating. We are happy to say, however, that as far as the medical witnesses on the recent Vanderbilt will case are concerned there have been no real grounds for complaint, but the discussion to which their testimony has given rise has been of value, not only to the profession, but to the public at large. Far from damaging the profession in the eyes of the people, it has tended to elevate it to its true dignity, by proving that the physician should be and is the trusted recipient of the most sacred of secrets.

Public opinion is now more than ever in favor of sustaining the "privileges" of the medical witness,

and of giving him a wider latitude for the exercise of his professional discretion. It will always be expected after this that the medical witness shall object on the slightest pretence, and if the objection is overruled, and he is compelled to testify, the *onus* will lie upon the court. In its legal aspects, then, this matter appears to be quite well understood. From a strictly professional standpoint the case is somewhat different, and it is in their attempt to discuss the subject from such a standpoint that the daily papers have committed many blunders. Their apparent inability to separate what was purely privileged professional testimony from what was not, was the principal cause for all the misunderstanding of responsibilities and the misconception of obligations. Pure science knows no sex, condition, age (and we were about to say color), but such science can only be understood and appreciated by scientific men. This is particularly the case with scientific medicine. Medical men, by their training and associations, are accustomed to look upon some things as very commonplace which to outsiders may be startling, if not disgusting. The description of autopsies as given in the Pathological Society, would hardly answer for the readers of a secular journal, and yet post-mortem examinations are necessary to obtain the necessary facts in a given case. In the Vanderbilt autopsy there was nothing done that was not necessary to have done under the circumstances. It was a plain, straightforward examination of all the important organs of the body. We have already proved that the facts as such were not privileged, and should not have been withheld from one party in the suit more than the other. The Surrogate decided that such facts were not, under the circumstances of the case, the exclusive property of the parties who paid for obtaining them. But it is not necessary here to go over our former ground of argument. What we desire to make clear is that it was the secular press that did wrong in spreading before the public testimony, the knowledge of which should be restricted only to the parties directly concerned. The inconsistency of condemning the character of the testimony, and at the same time of publishing it broadcast, is too apparent for reference. We do not expect that the public shall have any sympathy with strictly professional work. The people can never understand how cases can be curious, interesting, or rare, which to them are repulsive, disgusting, and obscene. The profession is of the opinion that the public has nothing to do with strictly professional matters, and hence has a right to protest against the course of the daily press, not only in the Will case in question, but in every other of a similar nature.

The difference between the public and the profession on these matters is simply this: with the first the interest centres in the individual; with the latter, in the abstract facts of the case. The autopsy or medical history of the commonest pauper, in a medical

sense, would be as interesting as that of Mr. Vanderbilt. But because the latter happened to be the subject of post-mortem examination it was considered perfectly proper by the daily papers to present a full account of the said autopsy, and then afterwards virtually criticise the doctors for making it.

When a prima-donna died recently, the public, because she happened to be a celebrated singer, at once became interested in the size of a uterine tumor which was found on post-mortem. We are sorry to say that an English medical journal was the first to start this very objectionable piece of intelligence. Would it not have been equally interesting to have reported the case without the name? But here is one of the main points in which the public and the profession differ.

Another question comes up in this connection, the answering of which is alike interesting to physician and attorney, and that has reference to what may and may not be privileged testimony. In this State the law provides that no physician shall be allowed to disclose any information which he acquired while attending a patient, and which information is necessary to enable him to prescribe for that patient, as a physician, or to act for him as a surgeon. In Arkansas, California, Indiana, Michigan, Iowa, Missouri, Minnesota, and Wisconsin substantially the same law prevails. These laws apply to every examination of a medical man, even as an ordinary witness, and no exception is taken unless by consent of the party confessing. It is proper to bear in mind in this connection that in this State, at least, the provisions of the law are "not applicable to the physician of a deceased person in a testamentary cause concerning the probate of the will of such decedent" (*Allen v. Public Administrator*, 1 Bradford, Surrogate's Reports, 521). The law, then, is quite explicit on this point, and gives the physician no choice in the matter. Although the Hippocratic oath leaves it discretionary with the physician as to what he may divulge,\* it is eminently just and proper that the law should sharply define the line. While it might be ordinarily safe to trust to the witness's judgment, in a given case, as to what should or should "not be spoken of abroad," as to what might or might not damage his patient, exceptions might occasionally arise in which there might be a serious error of judgment. It is well to understand that "the confession, in order to be protected against disclosure, must relate exclusively to such matters as are indispensable to the professional treatment of the patient. Communications made outside of this sphere acquire no immunity from having been entrusted to physicians, for at common law such are not deemed privileged, and wherever so recognized they are the

creatures of statutory enactment." (Ordroneaux's Jurisprudence of Medicine, and Grif. on Evidence, § 248.)

## Reviews and Notices of Books.

TRANSACTIONS OF THE MEDICAL SOCIETY OF NEW JERSEY, 1877.

Two essays of practical import, and a valuable report on the water supply of Essex County, adorn the Transactions, 1877, of the Medical Society of New Jersey, notice of which has already appeared in these columns. That of Dr. E. J. Marsh, of Paterson—"Hay Fever, or Pollen Poisoning"—deals pretty exhaustively with the literature of the subject, from Bostock to the recent experiments of Dr. Wyman, and then recounts a series of experiments by the writer himself, which appear to furnish pretty conclusive evidence of the correctness of Blackley's conclusion from experiments with flowering plants, grasses, and cereals, that the irritation is caused by pollen grains floating in the air. The action of the pollen of the order Gramineae was, on the whole, Blackley found, more distinct and well marked than that of other orders; but the quantity and irritating property both varied with variations of humidity, temperature, and other circumstances. Wyman's striking experiment with the pollen of Roman wormwood is cited; and then Dr. Marsh relates his own experiments with, and observations upon, the pollen of *ambrosia trifolia* and other varieties, with a brilliant series of microscopic observations as to the amount of pollen floating in the atmosphere. Having discussed these experimental data, Dr. Marsh concludes that hay fever is a proper pollen poisoning, and hence a local disease, not a constitutional one. As respects treatment, he has nothing new to offer.

The essay on the "Care of the Skin as a Means of Prevention and Cure of Disease," by Dr. A. N. Rogers, of Paterson; and the report by Dr. Lott Southard, on the "Essex Water Supply" (Drainage and Sewerage of the City of Newark and their Relation to the Causation of Diseases), are both papers of great scientific value and interest. The latter, especially, is one that should be carefully read by the public as well as by medical men, although many of its statements have only a local application. Taking Smith's estimate of the annual excreta as 630 pounds per capita, the amount of matter that the sewerage system of a large city has to carry off may be readily calculated. Krepp states the annual amount of excreta to the individual at 799  $\frac{5}{16}$  pounds—an average arrived at by comparing the statements of Liebig, Laws, Hoffman, Wilt, Way, Bousingault, Saussure, and others; but one that is probably a little in excess of the actual fact. The comparative analysis of well and Passaic river water, made by Prof. Wurtz, and the experiments of Dr. Frankland, showing the futility of filtering sewage-contaminated water, are cited and discussed at length in their relations to public health, and to the 33 per cent. zymotic mortality of Newark. It is conceded, in fact, by scientific men everywhere, that oxidation, accelerated by constant motion, is the only process by which sewage can be eliminated, and that even under such conditions running water, once contaminated with sewage, retains traces of the contamination after flowing for from 50 to 60 miles.

The Medical Society of New Jersey has also instituted an investigation as to the influence of maternal impressions upon fetal development, but no conclu-

\* The clause bearing on the point reads, "Whatever in connection with my professional practice, or not in connection with it, I see or hear in the life of men, which ought not to be spoken of abroad, I will not divulge, as reckoning that all such should be kept secret."—*Hippocratic Oath*.

sive facts have yet been contributed by the county reporters, although one or two curious and interesting cases have been reported.

**LECTURES ON FEVERS.** By ALFRED L. LOOMIS, A.M., M.D., Professor of Pathology and Practical Medicine in the Medical Department of the University of the City of New York; Visiting Physician to Bellevue Hospital, to the Mt. Sinai Hospital; Consulting Physician to the Charity Hospital; Late Visiting Physician to the Blackwell's Island Fever Hospital, etc., etc., etc. New York: William Wood & Company, 27 Great Jones Street, 1877.

THIS is the second volume of a series which has been promised by an eminent teacher in medicine. It comes to us as did the volume on "Diseases of the Respiratory Organs, Heart, and Kidneys," in the form of lectures. Of these there are thirty, and to the volume proper, a bibliography is appended. At the outset, we will direct attention to what we regard as commendable features of this book as a volume of lectures. The subjects have been studied systematically. We have, first, a brief introduction, and then the lecturer proceeds to give the morbid anatomy, the etiology, the symptoms, the differential diagnosis, the prognosis, and the treatment of the disease under consideration in the unvarying order here indicated. The value of systematic teaching cannot be overestimated. It disciplines the student to pursue his work after an approved and definite plan, thereby enabling him to know when his task has been thoroughly and completely performed. There are, unfortunately, both medical students and medical teachers, who travel a zigzag course in their studies and teachings all through life, and, although they may accomplish much, they do so at an immense sacrifice of time and energy. Such persons are not amenable to discipline in any form, but even they are usually willing to admit that it is with unalloyed pleasure they listen to, or read concise statements, systematically arranged.

Each class of fevers has been prefaced by a clear-cut reference to the theories regarding their nature. The author, however, has not entered upon an extended discussion of these theories. Perhaps he has been a little too wary in this respect. The error, however, if any has been committed in this direction, has been on the side of safety. Evidently, it has been his intention to give direct expression to the facts concerning each class of fevers, and the individual diseases belonging to that class, and then to leave the student and the reader to exercise their own judgment with reference to certain mooted points.

Those questions, both as regards theories and the phenomena of disease, which have been substantiated as facts, the lecturer does not hesitate to endorse by the use of his apparently favorite word "unquestionably." Those points which are still questionable, are for the most part passed without comment, the author doubtless believing it to be far better that the student should investigate for himself than that he should be loaded down with fine spun details which only tend to confuse. It might be urged by way of criticism, and with a certain degree of propriety, that the various subjects have not been spoken of with sufficient fulness to satisfy the wishes of the profession in general. In a measure such a criticism is warranted, but as we were about to say that the book is sadly deficient in many respects which bear only upon this point, we were reminded that its chapters are merely lectures and are not portions of a regular treatise on fevers. We have before us, therefore, a

book containing statements of practical facts relating to certain diseases, and the theories regarding their nature, mode of origin, and propagation, and arranged so as to be easily comprehended by the medical student. We also believe they will be read, without weariness by the daily practitioner. It is from this standpoint that our review is to be continued. The first lecture contains an introduction, a classification of fevers, and introductory remarks on typhoid fever together with a portion of its morbid anatomy. In the introduction the author presents the two prominent theories with reference to the nature of the poison, or poisons, which produce infectious diseases; these are the chemical theory and the theory of organisms, or the germ theory. Neither of these theories is fully adopted, and the author believes that investigation in this direction has scarcely begun. The classification has an etiological basis. We have *first*, CONTAGIOUS FEVERS, embracing typhus, relapsing, scarlet, miliary, small-pox, and measles; *second*, MALARIAL FEVERS, embracing simple intermittent, simple remittent, pernicious, dengue, and typho-malarial; and *third*, Miasmatic-contagious fevers, embracing typhoid and yellow.

The next six lectures are devoted to the further study of typhoid fever. Some knotty questions are developed upon these pages, but they are answered with great wariness. Indeed, this is one of the noticeable features of the book, and in the present mixed condition of recognized medical authorities we must regard it as rather commendable. For example, with reference to the question of contagiousness and spontaneous origin of typhoid fever, we find the guarded statement, "while on the one hand typhoid fever cannot be regarded as a strictly contagious disease, on the other hand it is not of spontaneous origin." This statement is at variance with the opinion of several eminent medical writers, but it is about the strongest expression that can be indulged in with safety when we study the writings of such men as Stokes, Pratt, Bouley, Jenner, de Mussy, Jaccoud, Murchison, Bouchardat, Guerin, and others, who stand upon almost as many different pedestals as there are different men.

Prof. Loomis's remarks upon the etiology of typhoid fever are terse and well placed; his description of the symptoms is compact and clear; his differential diagnosis is lucid and safe; his prognosis is well calculated to place the practitioner upon his guard; and his treatment is uncomplicated, but decisive, and that which, we believe, will commend itself favorably to the common sense of the experienced physician. To this general commendation of the treatment we wish to add that the author is sparing of drugs and observant of his patient. He evidently believes in a course of physic which is founded upon a careful study of individual peculiarities rather than the confident administration of medicine according to art.

Yellow fever is considered in lectures eight and nine, and malarial fevers consume the seven lectures immediately following. The three next lectures are given to the description of typhus fever, while an account of relapsing fever follows in lecture twenty-two. The remaining eight lectures are devoted to the consideration of the exanthematous fevers, including small-pox, scarlet fever, and measles.

The remarks already made with reference to the description of typhoid are equally applicable to the author's study of the other fevers. The bibliography will be found convenient for reference, and is an agreeable addition to the volume proper. The book is printed on heavy paper and in a large, clear type. It contains much practical knowledge, and cannot fail to be read by a very large proportion of the medical

profession, for a concise statement of facts, with only such qualifications as can be safely indulged in without endangering perspicuity, is always acceptable.

The method resorted to in preparing the book for publication—that is, by the aid of a stenographer, is not altogether new; but it must be acknowledged that the present volume is a most creditable illustration of what can be done in that manner, when the lecturer is thoroughly prepared to perform his part of the labor.

#### TRANSACTIONS OF THE VERMONT MEDICAL SOCIETY, 1876.

THE Transactions of the Vermont Medical Society for the years 1874, 1875, and 1876, just published in a pamphlet of 250 pages, evince a scientific spirit on the part of the profession in that State which augurs well for the future of physiological science in this country. This is particularly true of the proceedings of the sixty-fourth annual meeting at Montpelier, October 11 and 12, 1876, which contain an important paper by Dr. A. T. Woodward on Endometritis, its Causation and Treatment, in which he collates the recent literature of the subject with commendable thoroughness, and with an independence of criticism which is in striking contrast with the usual method of physicians in dealing with the accepted authorities in gynecology. Having once decided upon interior treatment, Dr. Woodward's plan is to swab out the womb with a solution of nitrate of silver, 30 grains to the ounce, about twice a month, making the first application four or five days after the cessation of the menses, and thus avoiding disturbance of that function. Although other alteratives may often be substituted with advantage, he prefers to try nitrate of silver first; not, however, to the exclusion of styptic iron, vitriolated tincture of lead, tannin and gallic acid in cases of menorrhagia, or of iodine tincture, nitric acid, and acid nitrate of mercury in the purulent variety. His experience, on the other hand, in the senile variety has been that iodine and nitrate of silver usually aggravate the trouble. When either of the varieties is complicated with hyperplasia, either limited to the interior or involving the cervix, he recommends the application of potassa fusa in the solid state to the vaginal cervix, as the surest and most rapid remedy, although one that must be employed with caution. The most obstinate cases of interior irritation encountered by Dr. Woodward have been those associated with ant-version or flexions; and in such instances the displacement must, he thinks, be corrected with a pessary of some kind, as a condition precedent to successful treatment of the inflammation or ulceration.

Dr. Emma H. Callender, of Middlebury, reports a curious and interesting case of hystero-epilepsy, which she pronounces unique in causation and in some of its features. The patient, a girl of 19, of delicate constitution, with antero-posterior curvature of the dorsal spine, subject to slight dysmenorrhœa, received a severe nervous shock from being plunged under water while bathing with some friends. There was complete loss of consciousness and pulse, with spasmodic and nearly arrested respiration. The convulsions lasted for six hours, and returned at varying intervals for a week, during which there was uninterrupted mania. The case went on for five months under general tonic treatment, the convulsions recurring at irregular intervals, without apparent cause, at any hour of the day or night. She ate well, slept well, and the menstrual function was regular. Although there was considerable uterine congestion, with hyperæsthesia in that quarter, Dr. Callender inclines to the opinion that

gastric irritation was the more immediately instrumental in bringing on the paroxysms, which gradually assumed a cataleptic form. At length, in October, 1875, he was attacked with severe pain in the region of the spinal curvature, which lasted for twenty-one days, and then departed as suddenly as it came. During this attack, neither the pulse nor the thermometer indicated any general fever, and for the first three days the natural functions were unimpaired. Menstruation came on normally during the twelfth day, but gave no relief. The treatment was anodyne, tonic, and nutritive; and since that date the patient has been uniformly well, with only two returns of the old convulsive paroxysms, occasioned by irregularities in sleep and food, in connection, in the first instance, with an exposure to the intense heat of a July day, and, in the second, with drinking too freely of sweet cider.

Dr. J. H. Smith's exhaustive paper on Cerebro-spinal Meningitis, read at the annual meeting in 1874, is a compend of the literature of that disease which will be found valuable for purposes of reference; and Dr. George Dunsmore's paper on Syphilis must be classed in the same category. So with Dr. Atwater's dissertation on Insanity, and Dr. Putnam's on Sanitary Reform. The curious feature of the pamphlet, however, is a savage "Criticism on the Diet Theory of the Origin of Typhoid Fever," contributed by Dr. Dunsmore, which will repay perusal as a polemic directed against the spore (germ) theory and its numerous disciples, among whom is Dr. Putnam, who bases his argument for sanitary reform in Vermont upon the putrescent origin of scarlatina, typhoid fever, etc.

#### FAT AND BLOOD, AND HOW TO MAKE THEM. By S. WEIR-MITCHELL, M.D. Philadelphia: J. B. Lippincott & Co. 1877.

THIS little book is an amplification of the article on "Rest in the Treatment of Nervous Diseases," which appeared in Seguin's Series of American Clinical Lectures, and contains a minute description of the author's method of treating anemia, or rather those cases of anemia that are complicated by nervous exhaustion, spinal irritation, or hysteria. The treatment consists in a combination of tonic influences, viz., absolute rest in bed, seclusion from friends, generous diet, massage, and electricity. None of these are new, but their combination in the way the author recommends does not seem to have been hitherto thought of. In some of the cases treated the success attained has been wonderful. Dr. Weir-Mitchell does not claim that his mode of treatment is applicable to all cases of anemia; but those which will be benefited by it are exactly the ones which prove rebellious to iron, bitters, change of air, etc., etc., and constitute the despair of the practising physician.

The details of the treatment are given with the utmost minuteness, and the book is on that account all the more likely to prove interesting and valuable to the busy practitioner.

LIBRARY OF THE MEDICAL INTERNES OF THE HÔTEL-DIEU.—The Municipal Council of Paris has donated the sum of 2,000 fr. to the library of the Medical Internes of the Hôtel-Dieu. A similar subvention was asked for the library of the pharmaceutical internes, but was refused on the ground that the pharmacists have not yet raised their library to the standing required by the by-laws of the Municipal Council before pecuniary aid can be furnished.

## Reports of Societies.

### NEW YORK ACADEMY OF MEDICINE.

*Anniversary Meeting, Nov. 15, 1877.*

DR. S. S. PURPLE, PRESIDENT, IN THE CHAIR.

THE exercises of the evening were opened by prayer by REV. DR. TUCKER.

"THE INFLUENCES WHICH ARE ELEVATING MEDICINE TO THE POSITION OF A SCIENCE."

DR. T. GAILLARD THOMAS delivered the anniversary discourse, in which he studied the history of medicine from the earliest periods of civilization down to the present time.

It was in the land of Egypt that medicine as an art had its birth, and from thence it came down through Jew, Greek, Roman, and Arab, until the accumulated experience of the ages was enveloped in the night of the dark ages.

But all the records of experience were not at that time swept away. If a dividing line could be drawn between ancient and modern medicine, between medicine as an art and medicine as a science, it would be at about the latter part of the sixteenth and the commencement of the seventeenth centuries.

The three great events which contributed most towards elevating medicine to the position of a science were the introduction of inductive philosophy, the utilization of the microscope, and the discovery of the circulation of the blood. That was the tripod upon which in the beginning rested the new-born science of medicine, and they were the three great events which marked a new era in its history.

The establishment of inductive philosophy exerted a marked effect upon methods of thought and investigation.

It soon became evident that moral and physical science were to combine in elevating our noble calling. The microscope lent precision to what had been only confused facts, and opened up a microcosmic universe before unknown. The eyes of the brave Vesalius were as keen as ours, but by this invention ours had become a thousand times more extended than his. If we were to lose the influence of the microscope all progress in medicine would cease.

Harvey demonstrated the circulation of the blood, while his opposers simply used argument. Up to that time medicine existed and flourished as an art, but at no time could it be dignified by the name of science. Then, by slow laboring degrees, each man working some isolated strand into the structure, here a little and there a little, very gradually the science began to take form and grow. Once securely established, it had made fair and satisfactory progress. But medicine would never become a pure and exact science. It must exist as a combination of science and art.

Without the science the art would remain as formerly; without the art the science must stand a profitless and useless tissue of speculation.

Science consisted of absolutely accurate knowledge, which rested for its certainty upon immutable laws. Art consisted of the application of the precepts of science to a practical end or purpose. In art truth was a means to an end; in science it was the end itself.

At the present time the most marked feature of medicine, and that upon which more than any other its

foundation should be formed, was the subordination of theory to experiment; accepting nothing as fact which could not give evidence of truth to the senses of the investigator.

To physical science was medicine indebted for its more marked progress during the present century. Physical science recognized no fact directly or indirectly, which could not be demonstrated to the senses. The multiform benefits which flowed from mechanical inventions were considered, and special attention directed to the mariner's compass and to the telescope. The discovery of gunpowder had contributed largely to the progress and development of medicine as a science. Reference was made to the influence exerted by auscultation and percussion, by the ophthalmoscope, the spectroscope, and the sphygmograph.

The two departments in which special labor of late had been performed were medical chemistry and experimental physiology. Attention was directed to the progress which science had given to obstetrics, and the work of William Hunter upon the gravid uterus was regarded as the corner-stone. A glance was made at the therapeutical department. It was not to the discovery of specifics that scientific research should be devoted, but to the production and use of remedies which gave us a more intimate knowledge of disease, and assisted in its prevention as well as in its general management. Trying those specifics which the shallow enthusiasts of our profession were constantly shouting could not assist in promoting scientific medicine.

The lesson to be learned from a study of the history of medicine was, that it had gradually advanced from art to science through the adoption of means which rendered all theories subordinate to physical demonstration, and recognizing nothing as fact which could not be directly or indirectly made evident to the senses.

America heretofore had done too little for medicine as a science. The day had come when the country which had done so much for the art of medicine should do something for its science. That such men would live in the future among us, we all hoped; but to believe that such men had lived among us in the past, no one had the hardihood to maintain.

The Academy of Medicine should recognize as one of its highest functions the encouragement and guidance of willing hands among the young physicians of America.

#### LENGTH OF TERM IN MEDICAL COLLEGES.

Much was heard nowadays concerning an increase in the length of the college term for medical students. No more industrious and active class existed among us than the medical students of the United States, and if they did not go forth from the present curriculum well qualified in their profession, it was no fault of theirs, but the fault was among the teachers. If, therefore, reform was to be brought about, if any great results were to be reached, let the axe be laid at the root and not upon the branches of the tree.

Let more be taught in laboratories, and at the bedside, and less in the lecture-room. Let the students be made to work and observe as well; incite them to personal investigation rather than send them forth with brains teeming with multiform theories and a mass of crude material poured into them from the rostrum of the lecture-room.

On motion, made by Dr. Fordyce Barker, the Academy extended a vote of thanks to Dr. Thomas for his learned address, and referred it to the Council for publication.

The benediction was pronounced by the Rev. Dr. Tucker.

## OBSTETRIC SECTION.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, November 19, 1877.*

DR. ISAAC E. TAYLOR, CHAIRMAN.

"DOES MORPHINE EXERT ANY DELETERIOUS INFLUENCE UPON THE CHILD WHEN ADMINISTERED TO THE MOTHER DURING PARTURITION?"

DR. SALVATORE CARO read a valuable paper upon the above subject, and drew attention first to the fact that the primary effect produced by morphine was upon the nervous system. Administered in proper doses, it was simply an anodyne and agreeable stimulant. When used with the intention of producing pathological rather than physiological effects, it reduced the action of all the organs except the skin, and in that manner diminished the oxygenation of the blood, and such deleterious effect might be transmitted to the child. The causes which contributed to the production of asphyxia in the child during labor were noticed—such as obtained in almost all tedious labors, etc. Cases were related in which morphine had been used in quantities varying from one-half to one grain in from five to sixteen hours in the first stage of labor. Those were cases mostly in which instrumental delivery became necessary. The child in each instance had the appearance at birth of being exsanguinated, and death was believed to be due to conditions connected with the parturient process rather than to the effect of the morphine. In no single case had Dr. Caro noticed symptoms of narcosis in the child, after administering morphine or opium to the mother during parturition, and his belief was that the deleterious effects upon the child attributed to the influence of the drug were due to the retarded labor rather than to narcotism. A series of cases was related in which morphine was administered during the first stage of labor only, and for the purpose of relieving rigidity of the os, quieting annoying pains, etc. In all the cases the child was born in a prime condition. The morphine was given by the mouth, in doses of  $\frac{1}{2}$  or  $\frac{1}{4}$  grain, at intervals of varying length, and the entire quantity administered in each case was as follows:

Case	I.—2 grains in 12 hours.
"	II.—1 grain in 7 "
"	III.—1 " 4 "
"	IV.—3 grains in 11 "
"	V.—3 " 14 "
"	VI.—3 " 20 "
"	VII.—1 grain in 18 "
"	VIII.—5 grains in 20 "

Those were the more notable cases, and the last was worthy of special mention. In that instance the Doctor purposely produced full narcosis in the mother, in order to see what the effect would be upon the child. The pulse was reduced to 60, the respiration to 16, and the pupils were markedly contracted. No ill results followed, although at the time he was afraid that he had produced fatal narcosis. Respiration in the child was quickly established, and the infant was healthy in every respect. On account of severe after-pains, it was necessary to continue the morphine in  $\frac{1}{4}$  and  $\frac{1}{2}$  grain doses for forty-eight hours. The child, from its birth, nursed from the mother, and without producing any symptoms whatever of narcosis.

Dr. Caro regarded the drug as a safe one to be used either during pregnancy or during labor.

DR. CUREN remarked that he had been in the habit of using morphine during labor, sometimes for the purpose of suspending labor, sometimes to sup-

port and sustain the mother; but he had not seen any result produced upon the child which looked like narcotism.

DR. JOEL FOSTER remarked that he had been accustomed to use morphine for the purpose of allaying annoying pains, and had given it in one large dose, thus hoping to give the woman a little rest. He had never seen any ill-effects produced upon the child.

DR. POST preferred to use a few large doses rather than small doses frequently repeated, if the pains were annoying. He had not seen anything which would lead him to believe that the child was suffering from narcotism in consequence of its administration to the mother.

DR. PERDY had not hesitated to give opium or morphine during labor, and had never seen any deleterious effects produced upon the child.

DR. O'SULLIVAN and DR. J. C. PETERS had been accustomed to use some preparation of opium during labor, in cases which seemed to require it, but had not noticed any undesirable effect upon the child.

DR. MUNDÉ favored the use of morphine hypodermically rather than by the mouth. He thought that the effect produced by 10 or 15 ℥ of Magendie's solution of morphia, given hypodermically, was fully as severe upon the mother as to administer small doses by the mouth. It had been urged by some that morphine underwent a change in the stomach, was "digested" by the mother, hence could not narcotize the child; whereas, when administered hypodermically, it passed into the circulation almost at once, and the child might receive its narcotic influence. In the discussions which of late had been held in this city upon the question before the Section, he was of the opinion that those who took the view that morphine did not act upon the child when given to the mother during labor were in the ascendancy, both with reference to numbers and argument. Reference was made to the experiments made by Wigglesworth, of Liverpool, in which it was thought to be shown that morphine, under certain conditions, acted as a stimulant to the uterus during labor; hence the article most desired. According to his own experience, no deleterious effects had been produced upon the child.

DR. HANKS thought there was one difficulty in deciding this question, from the fact that we never administered morphine to the mother without a necessity, and the necessity in the case might be sufficient cause for all the unpleasant conditions present in the child when born. He had never hesitated to use morphine in the first stage of labor, in such doses as seemed judicious, and had never seen, so far as he knew, any unpleasant effects produced upon the child. He did not use it hypodermically, unless the stomach was very irritable.

DR. F. V. WHITE and DR. SELL corroborated the testimony already given by stating that they had not seen any ill-effects produced upon the child by the use of opium during labor.

DR. KENNEDY remarked that he commonly employed Dover's powder, in doses of 12 or 15 grs., or Magendie's solution of morphia, in doses of 15 or 20 drops, for the purpose of allaying annoying pains during the first stage of labor, and giving the woman rest. He had not seen any evil effects produced upon either the mother or the child.

THE CHAIRMAN remarked that the object for which he administered opium during the first stage of labor was to secure rest. It was both a sedative and stimulant to the uterus. He did not give it for the purpose of removing rigidity. Reference was made to a case

of rheumatic neuralgia of the uterus in a pregnant woman, treated in 1842 by the use of hypodermic injections of morphine, and without injury to the child.

Chloroform and opium were regarded as uterine stimulants. He did not partake of the view that the child could be sacrificed by the use of morphine during labor; it made no difference whether the membranes were ruptured or remained intact. He had frequently given morphine and chloroform as a uterine stimulant, instead of resorting to the forceps, when the head was well into the cavity of the pelvis. He preferred the watery extract of opium to morphine, because of the many unpleasant effects which were liable to follow the latter.

Dr. Caro's paper was referred to the Academy, and the Section adjourned.

## Correspondence.

### BOSTON MEDICAL CHARITY.

TO THE EDITOR OF THE MEDICAL RECORD.

DORCHESTER, BOSTON, MASS., NOV. 13, 1877.

MY DEAR SIR:—In your editorial on medical charities in the RECORD of the 10th inst., you remark that you are inclined to think that my statement, in the *Boston Medical and Surgical Journal* of November 1st, that twenty-seven per cent. of the population of Boston are treated at the dispensaries and out-patient departments of hospitals, is a mistake, and "that it is more nearly twenty per cent." The data upon which I based my calculations were drawn from the reports of the various institutions for 1876, and from the State census of 1875. The population of Boston at that time was 341,919. The number of medical beneficiaries in 1876 was 92,977, or slightly more than twenty-seven per cent. of the population. The *estimated* population of Boston, January, 1877, was 352,758. If this number be taken as the basis of the calculation, it will appear that the medical paupers constitute more than twenty-six per cent. of the population.

Your estimate of twenty per cent. hardly seems warranted by these facts.

Permit me to give you a few additional figures upon this subject. If from the estimated population of the city in January, 1877, given above, we subtract 92,977—the number of the non-paying residents—there will remain 259,781—the number of the paying population. The number of physicians in the city in January, 1877, was 782, or one to 332 paying inhabitants. Perhaps it was a knowledge of these facts that caused me, in the paper you have noticed, to confine my attention pretty closely to a discussion of the matter from a pecuniary standpoint.

Very truly yours,  
ORVILLE F. ROGERS.

### HOW TO RESTORE THE SCALE OF THERMOMETERS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Physicians are frequently troubled by the scales of their thermometers becoming indistinct, the pigment in the marks wearing out. The scale may be made distinct again by painting it with an alcoholic solution of any aniline color. Make two or three applications, let the color dry, and then rub off with a dry cloth. The aniline will fasten itself on the roughened glass of the scale alone, making each line

show distinctly. Water will not remove the coloring matter, which, when it fades, may be easily renewed.

Respectfully,

MAURICE PERKINS, M.D., *Prof. of Chemistry.*

UNION COLLEGE, SCHENECTADY, N. Y.

## New Instrument.

### AN IMPROVED OPHTHALMOSCOPE.

By D. E. DUDLEY, M.D.

NOTWITHSTANDING the ingenious designs—practical and commodious forms—which characterize many of the more modern ophthalmoscopes, particularly those so nicely devised and arranged, both by Dr. Loring and Dr. Knapp, of this city, I take pleasure in presenting to the profession a modified one, which, while it obviates some objections, will, I am persuaded, be found to embody all the advantages possessed by those so justly celebrated of the above-named authors.

While respecting the optical and general features of the Loring and Knapp instruments, the essential of what I may call my modification consists in arranging two equal discs containing the dioptric trains—*positive and negative*—in a form which, in my opinion, is more compact and convenient for manipulation.

This result I have obtained by collocating both discs upon an eccentric pivot, allowing thereby an overshoot or projecting margin of each—the one to the right, the other to the left—from the lateral borders of the inferior third of the instrument. Upon this they are rotated and managed with all the ease and facility which distinguish those of the single disc.

Of the advantages accruing from this arrangement, I need scarcely speak. The discerning ophthalmologist will at once perceive them. By it he can adopt the form and construction of any mirror his fancy or experience may lead him to prefer. The lenses of the dioptric media, while retaining that medium aperture compatible with efficiency, may, through their *plus* and *minus* combinations, amount to a series more than sufficient for every exigency, and the instrument still kept in due bounds with regard to size; in fact, considering the number of combinations, it is the smallest of ophthalmoscopes.

The focal index can, of course, be arranged either by the metrical or English enumeration, and made to read *positives* upon one side, and *negatives* on the reverse, or both placed upon the back of the instrument, according to fancy.

This ophthalmoscope I have had made by Miller Brothers, opticians, who, in executing my design, have exhibited much skill and elaborateness of workmanship.

NEW YORK, Nov. 20, 1877.

### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from Nov. 18 to Nov. 24, 1877.*

CLEMENTS, B. A., Major and Surgeon. Assigned to duty at Camp Douglas, U. T. S. O. 131, Dept. of the Platte, Nov. 14, 1877.

GIBSON, J. R., Major and Surgeon. Assigned to duty at Fort D. A. Russell, Wy. T. S. O. 132, Dept. of the Platte, Nov. 16, 1877.

KOERPER, E. A., Capt. and Asst. Surgeon, assigned to duty at Fort Sanders, Wy. T. S. O. 133, Dept. of the Platte, Nov. 17, 1877.

MUNN, C. E., Capt. and Asst. Surgeon. Assigned to duty at Sidney Barracks, Nebr. S. O. 132, C. S., Dept. of the Platte.

WINNE, C. K., 1st Lieut. and Asst. Surgeon. Assigned to duty at Fort McPherson, Nebr. S. O. 132, C. S., Dept. of the Platte.

MOSELEY, E. B., 1st Lieut. and Asst. Surgeon. Assigned to duty at Camp Robinson, Nebr. S. O. 132, C. S., Dept. of the Platte.

NEWLANDS, W. L., 1st Lieut. and Asst. Surgeon. Assigned to duty at San Diego, Cal. S. O. 142, Div. of the Pacific and Dept. of California. Nov. 14, 1877.

CORBUSIER, W. H., 1st Lieut. and Asst. Surgeon. Assigned to duty at Camp Sheridan, Nebr. S. O. 133, C. S., Dept. of the Platte.

ART IN HOSPITALS.—The *Lancet* for October 20th describes a picture-frame designed by Dr. Lawrence Hamilton, whose efforts to promote the artistic decoration of hospital wards have attracted considerable attention in England, with special reference to economy and to sanitary requirements. The frame is made of metal, and arranged for the reception of two pictures, separated by a diaphragm, which, in place of being covered with glass, should be well varnished both at the front and at the back. It may be japanned of any color, or ornamented with any designs that taste may suggest. Dr. Hamilton claims for his invention the important advantages that it is non-absorbent, and that it may be cleaned with hot water, or readily disinfected with carbolic-acid water, or even heated in a dry oven—a treatment to which ordinary frames cannot be subjected. The economy of having each frame carry two pictures, which may be reversed at convenient intervals, is obvious at a glance. It is a familiar fact to physicians that the backs of picture-frames hung in the ordinary way, with the inferior edge against the wall, become, as Dr. Hamilton styles them, aerial dust-bins, sometimes undisturbed for months, in which large quantities of dust, loaded perhaps with the germs of contagion, are permitted to accumulate; and what hospital dust actually is has been described recently by M. Pasteur, after a brilliant series of microscopic observations. The inventor insists that pictures in hospitals should be hung parallel with the wall—not at an acute angle; but this appears to be scarcely necessary with backs formed by varnished or glazed pictures, which may be turned and dusted as often as necessary; particularly as, unless hung inconveniently low, a glazed or varnished picture, as well as one protected with glass, is resolved into a mere blur of

drawing and color when viewed at an angle either acute or obtuse as respects the optic axis. The subject, however, is pregnant with one valuable suggestion, namely, the impropriety of framing hospital pictures in frames of porous wood, unplanned at the back, and covered in part with common brown paper—consequently, adapted to absorb and retain the moisture of an atmosphere often saturated with the impurities and infectious elements of disease.

PHOSPHORESCENCE OF QUININE.—Prof. Landerer writes to a pharmaceutical journal in Paris, that, if sulphate of quinia, placed upon glazed paper lying upon a silver plate, is heated carefully to from 50° to 62° C. (122° to 144° F.), and then stirred in the dark with a glass rod, it emits a phosphorescent light of extraordinary beauty, which lasts until the heat is exhausted. Valerianate of quinia, as readers are aware, behaves in a similar manner at an ordinary temperature, its crystals becoming phosphorescent when rubbed or pounded in a mortar.

EFFECT OF MAGNETISM ON INSECTS.—Dr. John Vansant, of New Orleans, writes to the *Philadelphia Medical Times* of a recent date, giving an account of a series of experiments relative to the action of the magnetic current on insects. One of these experiments was conducted upon a spider, with a mere toy magnet. On placing the instrument, armature removed, in such a position that the insect was between the poles, it stopped almost instantly, and in a few seconds became perfectly motionless, but, two or three minutes afterwards, commenced to move its legs and to lift and depress its head in a very singular manner. In about five minutes it ceased its movements altogether, and was apparently dead. He has killed worms and insects in this way frequently, and concludes from his experiments that terrestrial magnetism must exercise an important influence upon the functions of animals.

SMALL-POX IN BORDEAUX.—A moderately severe epidemic of variola has been raging in Bordeaux for some time past. The epidemic was latent for about six months, but has become active of late. The Hôpital Saint André is full of patients, all of whom come from the same quarter of the town—the neighborhood of the place Saint-Julien and the Rue Henri IV.

THE HOSPITAL GAZETTE AND THE ARCHIVES OF CLINICAL SURGERY is the name of the new journal formed by the consolidation of the *Hospital Gazette* with the *Archives of Clinical Surgery*. This new periodical contains 24 pages of printed matter in octavo form. The editors, Drs. Bermingham and Lyons, are assisted by able collaborators.

EXAMINATION AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.—During the past collegiate year, of the 87 candidates who underwent the primary examination for the fellowship, 43 were rejected. At the final examination 27 out of 37. At the primary examination for the membership, out of 792 candidates, 246 were rejected. At the final examination, out of 569 candidates examined, 356 passed.

THE CRESCENT AND THE CROSS, AND THE RED CROSS.—Active efforts are now being made in this city to furnish supplies of all kinds for the sick and wounded in the Russian and Turkish armies. The Red Cross Society, a branch of the one founded by the Empress of Russia, furnishes relief for the Russian sick and wounded, while the Crescent and the Cross Society proposes to minister to the wants of both contending sides.

## Original Lectures.

### DISEASES OF THE NERVOUS SYSTEM.

A LECTURE DELIVERED AT BELLEVUE HOSPITAL  
MEDICAL COLLEGE.

By C. E. BROWN-SÉQUARD, M.D.

EFFECT PRODUCED WHEN BRAIN DISEASE STRIKES AT THE ORIGIN OF NERVES—DIAGNOSIS OF HEMIPLEGIA—DISTINCTION BETWEEN DISEASE OF ONE-HALF OF THE SPINAL CORD AND DISEASE AT THE BASE OF THE BRAIN—NEW SYMPTOM—EFFECT UPON TEMPERATURE, ETC.—ZONE OF ANÆSTHESIA—DISTURBANCES OF OTHER ORGANS: KIDNEYS, HEART, LUNGS, ETC.—ABSENCE OF CONVULSIONS IN DISEASE OF THE PONS VAROLII—DIAGNOSIS OF DISEASE OF THE CRUS CEREBELLUM—PARALYSIS A CONSTANT SYMPTOM OF BRAIN DISEASE.

(Reported for THE MEDICAL RECORD.)

GENTLEMEN:—At the last lecture I referred to a number of cases, with the purpose of showing that any lesion in the side of the brain can produce the greatest variety of forms of paralysis—the greatest variety as regards the extent, the degree, and the persistence of paralysis. This, of course, has led a number of you to think it to be extremely difficult to make a diagnosis of the locality in the brain of the disease which produces paralysis. No doubt, it is extremely difficult, but as you will see, from what I shall say to-day, there are features which can lead to diagnosis of locality of lesion, even when what we observe is entirely in opposition to the views which are generally accepted.

But before I speak to you of those facts which lead to diagnosis of the seat of the disease that has produced the paralysis—the symptoms of the disease—I have a few words more to say upon a point which escaped notice in the previous lectures. It is this: the theory published by Dr. Broadbent has been put forth with the view of explaining certain difficulties which we find as regards the seat of paralysis. As I told you yesterday, in most cases of brain disease producing hemiplegia, the hemiplegia consists almost exclusively of paralysis limited to the arm, the leg, and to some of the muscles of the face. There are many parts of the body which escape paralysis in the immense majority of cases of disease of the brain. Those parts are the muscles of the trunk, the muscles of the neck, those muscles which go from the trunk to the limbs—the arms or the legs. Those muscles escape paralysis more or less, rather more than less, in the immense majority of cases. Dr. Broadbent has tried to explain this fact in admitting that there are certain parts of our body which depend on a centre located in the medulla oblongata or at the lower part of the pons varolii, and which has the power to act upon both sides of the body. So, admitting that one side of the brain is destroyed totally, including that nerve-centre which is the corpus restiformis upon the same side, the corpus restiformis upon the other side is alone sufficient to move the two sides of the body, and thereby the muscles which have escaped paralysis. The view is certainly true in a great measure, but it is faulty in this; Dr. Broadbent, as well as most medical men, considers the corpus restiformis as a motor-centre. The reality is, as I hope to be able to demonstrate, that a small part of one side of the brain is sufficient for both sides of the

body, not only for the muscles which escape paralysis, but for the muscles of the limbs as well.

I now pass from this to what I have to say regarding the significance of certain symptoms in the diagnosis of the seat of the brain disease which causes paralysis. There is one fact, very important indeed for you to understand fully before I enter into details upon this point. As you well know, there are nerves arising from the base of the brain, nerves which serve as centres, which serve for general tactile sensibility, and also as nerves of motion. Then you must make a distinction between cases of paralysis of those nerves dependent upon disease which strikes at the very place from which those nerves arise, in which case the trunks of the nerve itself or its immediate roots within the base of the brain are implicated, and those cases in which these nerves are paralyzed when the lesion is beyond the place of their entrance into the base of the brain.

Suppose, for instance, a lesion occurs in the medulla oblongata in the immediate region where the root of a motor-nerve has its origin; if the disease strikes there, it of course destroys some of the fibres of the nerve, and it destroys the cells also from which the nerve-fibres arise. But let the disease be located in another part of the brain—at a point beyond—where there are no nerve-fibres arising which form a connection with the nerve which goes down from the medulla oblongata, then you will have a result completely different from what you have when the cell itself of the motor-root is struck by the disease. In those cases of paralysis of nerves in the base of the brain dependent upon destruction of the cell which gives rise to the nerve-fibre, or striking the root itself before it reaches these cells, you have just the same result produced as if the nerve-trunk had been affected outside of the brain.

Something quite different takes place when the disease is beyond the origin of these nerve-fibres. In what I have already said in a previous lecture with reference to paralysis of the muscles of the face, muscles of the eye, paralysis in the tongue, in the neck, and elsewhere, I had in view only those cases in which the paralysis depended upon disease inside of that zone or layer of nerve-cells which gave rise to the motor nerve-fibres going to the tongue, to the eye, etc. There is no question that, when you find disease in the base of the brain striking the nerve or its roots before they reach the cells of origin, there will be paralysis upon the same side of the body in which the disease is situated. It is quite evident that it must be so. You have a cause acting the same as if you had divided the nerve itself outside of the brain, and of course you have paralysis of the nerve.

In what I have now to say, you will find that what I have just mentioned is of the greatest importance; I will illustrate at once the meaning of this. You will see that in case of disease of the pons varolii, for instance, a little above the place of origin of the facial nerve—the nerve which acts upon the muscles which give expression to the face—there is a characteristic condition produced.

If the disease is upon the roots of the facial nerve, or upon the cells which give origin to these fibres of the facial nerve, the muscles of the face upon the same side of the seat of the disease will be affected. If the disease is elsewhere, as a rule, the muscles of the face upon the side opposite to the seat of disease will be affected. So you see that in disease in the same organ, the pons varolii, you may have results just the reverse of each other. The face may be paralyzed upon the right or upon the left side; but as regards

the limbs, as a rule, you will find them paralyzed upon the side opposite to the seat of the lesion.

What I wish you now to fully appreciate is the fact that, when the disease strikes at the origin of the nerves, necessarily it produces paralysis in the nerve; that nerve may be the olfactory, the optic, or any one of the cranial nerves. In any of these cases the very same thing will occur with regard to the seat of the paralysis; it will always be upon the same side with the lesion.

#### DIAGNOSIS OF HEMIPLEGIA.

I come now to the diagnosis of various cases of hemiplegia. I must first point out the fact that disease of one-half of the spinal cord, as well as disease at the base of the brain, can produce hemiplegia, and how you are to determine where the seat of the disease is, is what I will try to explain. You may find two persons struck down suddenly with loss of consciousness, sometimes with convulsions — convulsions are not essential, however—and after their recovery from the shock, you find that there is paralysis, in both cases, on one side of the body. We will suppose that the right side is paralyzed. One of these persons makes grimaces upon the side of the face corresponding with the side on which there is paralysis of the extremities; so you may be inclined to think that there is paralysis of the face upon the opposite side.

#### NEW POINT IN DIAGNOSIS.

This point in diagnosis, so far as I know, has not been mentioned except by myself, and as it is a constant phenomenon in certain kinds of lesion of the spinal cord, I wish you to be quite aware that in that case there is merely an appearance of paralysis upon the side of the face opposite to that on which there is paralysis of the limb. If you pay attention only to the appearance of paralysis of the left side of the face and on the right side of the body, and establish the fact that the man has had an attack of apoplexy, loss of consciousness, etc., you will certainly, and quite naturally, according to the teachings of science until now, be led to admit that there has been somewhere in the brain a lesion which has produced all these symptoms. That may be a mistake, or it may be correct; because lesion in one-half of the spinal cord very near the medulla oblongata can produce all these symptoms. I will say at once that when you examine the face, you will find that the side which seems to be paralyzed is not the paralyzed side. You will find that there is no paralysis of the face upon either side in that case. You will find that the appearance of paralysis comes only from the fact that, on the side of the lesion in the spinal cord, there is simply a spasmodic state of certain muscles of the face.

In cases of spinal hemiplegia, paralysis of one side of the body, depending upon disease high up, and limited to one-half of the spinal cord, you will find that there is a series of symptoms such as I mentioned a moment ago. You will find features which certainly will distinguish these cases from cases of hemiplegia, depending upon disease of the brain. If you examine the patient carefully, you find that there is paralysis, and as I have supposed the lesion to be in the right half of the cord, the patient is paralyzed in the right limbs; but there is no diminution of sensibility. On the contrary, there is considerable increase of sensibility, as measured by the esthesiometer. The hyperesthesia may be extremely great. Indeed, in the case of one of my dear friends, Mr. Charles Sumner, at the two points in the spine which had been injured by a cane in an assault made upon him in the Senate

Chamber, both points of the instrument could be distinctly recognized, no matter how near to each other they were placed.

That kind of feeling—that of touch—may be increased considerably in many other cases; but in spinal hemiplegia the tactile sensibility is increased in the paralyzed limbs to a considerable extent.

Other kinds of feeling are also increased. Painful feeling is often considerably increased, and sometimes it is so great that a mere touch produces a scream. There is also an increase in the power of detecting differences of temperature. There is lack of power of enduring the contact of anything very cold, or very hot, as those things will produce decided pain. There is besides an increased sensitiveness to tickling. But there is another feature which will assist in making a diagnosis between this form of paralysis and that form dependent upon disease in the base of the brain, and that is the condition of the muscular sense. When the patient has but little power of motion the muscular sense is very good indeed, and he will know perfectly well where his limb is without the necessity of placing the hand upon it to determine its location.

Now, in the contrasting condition, there is loss of sensibility of all kinds. The loss may be absolutely complete, so that the patient is not able to feel any blow, prick, tickling, galvanism, etc.

As regards the temperature in the limbs, there is another distinguishing feature. You will find that the limbs are very much warmer where the muscles are paralyzed, and lessened in warmth upon the opposite side. There is then a double effect upon the temperature; increase upon the side of the lesion, and diminution upon the opposite side. But these are not the most interesting features of such cases. You will find that the face is warmer upon the side of the lesion; and that is because the fibres of the sympathetic nerves going to the blood-vessels of the head are divided upon that side of the spinal cord. There is higher temperature in the face, higher sensibility, and greater redness of the eye and ear. There is also a symptom to be observed in the eye; and that is dilatation of the pupil upon the side of the lesion. These are effects which we know will follow galvanizing the sympathetic in the neck. All these effects are found in connection with disease of one-half of the spinal cord.

The fact that the muscles are contracted is in consequence of the greater afflux of blood to the part; it is not due to changes occurring in the nerve-centres, but to the local fact of being fed far more abundantly than in health. Hence, they are in a state of greater tonicity, as it were; but there is no trace of paralysis on either side of the face. That fact will serve as a diagnostic feature between the form of hemiplegia depending upon disease of one-half of the spinal cord, and hemiplegia depending upon disease in the base of the brain. Besides, there are a great many symptoms of disease in the base of the brain which do not exist with disease affecting one-half of the spinal cord.

I now pass to other facts. In cases of disease of one-half of the spinal cord, you will find that there is usually a feeling of stricture about one-half of the body at a level with the seat of injury in the cord.

#### ZONE OF ANÆSTHESIA.

At that place there is something that can be recognized which is very interesting indeed, and which is in harmony with the view regarding the origin of nerve fibres. As the lesion in the spinal cord necessarily destroys some nerve-fibres which do not supply the

motor trunk, there is a zone of paralysis of sensibility at the level of the injury in the cord. Some of the sensory roots have been involved; hence the loss of sensibility in that circumscribed region. We have hyperæsthesia below and above the seat of the lesion, and a small zone of anesthesia at the place where the lesion occurs, so that the body is separated into *three* zones—*two* of hyperæsthesia, and *one* of anesthesia. Nothing of this kind is present in hemiplegia depending upon disease in the base of the brain. You can already see that diagnosis can be easily established, and you will see this much more clearly as I come to speak of the symptoms of hemiplegia depending either upon disease of the medulla oblongata, or other parts of the brain.

#### GENERAL SYMPTOMS.

When there is disease in the medulla oblongata, or pons varolii, there are general symptoms which are of great interest, not so much for diagnosis, as for prognosis. They are important in deciding upon the chances for restoration to health, and the chances of death; and also the means of treatment are not the same as when the disease exists in other parts of the brain. These general features are that, according to the seat of the disease in the base of the brain, there are nerves implicated which show where the disease exists. Supposing it to be in almost the entire length of the base of the brain, from the origin of the optic bands down to the spinal cord, you will find that all the nerves which take their origin in that part are more or less implicated in the disease. If you know what these nerves are, you can easily understand what the symptoms will be. I will simply mention that as the *third* pair of nerves is implicated, certain results will be manifest in the eye, and you will find the pupil affected, and the motion of the eye will be affected. Other nerves are implicated, and the effects are exceedingly complex, but they are in perfect harmony with the known functions of the nerves having their origin at the base of the brain. So the diagnosis may be perfectly clear, and you will find, as a rule, that the paralysis, instead of being upon the same side, as in the case of disease of one-half of the spinal cord, is upon the opposite side of the body. If there is loss of feeling, it is where loss of movement exists.

#### DISORDERS IN THE KIDNEYS, LUNGS, AND HEART, ETC.

But there are other features: there are disorders which take place in many of the organs of the body. The urinary secretion is disturbed; sometimes increased immensely, with or without the presence of sugar. When sugar is present, the quantity of urine is not so much increased as when the sugar is absent, but it may be considerably increased in quantity. We may have then both forms of diabetes—insipidus and mellitus. These two forms of diabetes are found in connection with all diseases in the base of the brain, but they may exist in connection with disease very far from the brain. To my knowledge, these forms of diabetes never exist when the spinal cord is the seat of disease.

There are many other features. I have shown that lesions of the pons varolii, or medulla oblongata, affect the lungs almost at once. That is the fact in most cases in which the lesion is made in animals. I may say that it is frequently so in man. One of the chief effects produced by lesion in the pons varolii in man is considerable congestion of the lungs. Another effect, which depends almost only upon lesion in the pons varolii where the *crus cerebri* comes into it, is hemorrhage into the lungs. This occurs very fre-

quently indeed; sometimes it is slight, and sometimes enough to destroy life rapidly. It was known that hemorrhage into the lungs occurred in connection with hemorrhage into the base of the brain, but it had been supposed that it took place because of the same alteration in the walls of the blood-vessels in the lungs as was present in the blood-vessels in the brain. My friend Professor Charcot and Bouilland made the great discovery that hemorrhage in the brain depended almost always upon the rupture of small aneurisms—miliary aneurisms. It was imagined, and it has been found to be the case, that the blood-vessels in the lungs also have the same kind of aneurismal dilations, and it was thought that in those cases in which hemorrhage, either small or large, took place in the lungs, after having hemorrhage into the brain, it was dependent upon the same cause. Without doubt it is so in some cases, but, as a rule, when the hemorrhage in the lungs appears very quickly after that which occurs in the brain, it is produced in a direct manner by an alteration in the circulation in the lungs.

I have asserted that the breaking of blood-vessels in the lungs depends upon this change. The arteries and veins become so contracted that there is not a trace of blood in them, and then the congestion goes so far that a capillary breaks, and there is hemorrhage. It is one of the causes of death in disease of the pons varolii, or perhaps at other parts of the base of the brain.

This cause of death has not been sufficiently guarded against, and it very frequently happens that no examination of the chest is made in these cases. This is a fault which I myself have fallen into, but it should always be kept in mind that great alteration can take place in the lungs in consequence of disease in the base of the brain.

The opposite may occur, perhaps, in one out of ten cases.

We have, then, *first*, congestion of the lungs, and, after a time, there may occur foci of inflammation in connection with acute disease in the base of the brain. As the patient has more or less difficulty of breathing, on account of the brain disease itself, the disease of the lungs passes unnoticed, and no local treatment is applied which could be of great service to the patient. I have no doubt that we may recall to memory a great many cases published as fatal cases of disease, occurring at the base of the brain, which terminated fatally, not because of the brain disease itself, but because of subsequent disease of the lungs, which passed unnoticed during life.

There is, therefore, in cases of disease of the brain, an effect, which is of great importance, produced upon the lungs. Another effect which is of great interest can take place. As you well know, the *par vagum* takes its origin in the medulla oblongata. And you know that if this nerve is galvanized, the heart's action is arrested. Well, acute disease in the medulla oblongata, or close to it in the pons varolii, will produce irritation of the *par vagum*, and may reduce the heart's action to such an extent as to prove fatal. You doubtless know that there are a number of cases upon record in which death was caused by pressure upon the medulla oblongata, from displacement of bones, or some other cause. There is this feature, then, in connection with disease in that region: that is, there is a diminution in the beat of the heart—a diminution in force rather than a diminution in speed.

There are other features belonging to lesion in those parts. As you well know, the *œsophagus*, the *pharynx*, and the *larynx* are supplied with nerves which arise from this region. There may be spasm

in these organs. In a case which I shall always remember, for it occurred in the person of a most dear friend of mine, there was such spasm in the œsophagus that it was absolutely impossible to feed him by the mouth; not even a tube could be passed through the œsophagus, so great was the spasm, and we were obliged to sustain his life by nutritious injections into the bowels. The material used was the fresh pancreas of an animal, with hashed meat. The fat is removed from a fresh pancreas, and the influence of the remaining portion upon nutrition is pretty nearly the same as if a series of meals were taken in the usual manner. In the case of my poor friend, life was maintained eight days solely by this process of eating.

There is, therefore, an effect produced upon these parts by disease situated at the base of the brain, as mentioned. There are other features of interest. You may diagnose very easily, for instance, whether there is disease present upon the origin of the trigeminal nerve, by change in the state of the cornea. The cornea becomes somewhat inflamed, and after a time the eye may be destroyed. You already know that Magendie has long ago shown that when the trigeminal is divided in an animal there will follow impairment of nutrition in the eye, and after a time the organ will be lost. Magendie also has shown that all the senses are affected by division of the trigeminal—the sense of sight, of audition, of olfaction, as well as the sense of taste. This conclusion of Magendie would not have been drawn had he been familiar with the phenomenon of the loss of function. When the trigeminal is diseased or divided, the nerve-fibres produce no action, and that result is quite sufficient to produce loss of sensation, and the nutrition of other organs of sense is disturbed by such result.

A blow upon the frontal nerve, for instance, may be sufficient to cause loss of sight, and, besides, a considerable alteration in the nutrition of the eye. Irritation produces loss of all the senses, and in that case it may be from reflex action affecting the blood-vessels, thus changing the nutrition. Disease of the optic thalamus, for instance—a part far away from the origin of the trigeminal—can produce by its effect, through the trigeminal, an alteration of sensation, and an alteration of nutrition in the cornea and loss of the eye, the same as if the trigeminal itself was diseased or divided. Therefore, when you find loss of nutrition upon either side of the face, and alteration of sensation upon that side, you can judge that the cause or lesion is upon the side where the trigeminal is disturbed.

Now comes something in the way of diagnosis that is of the greatest importance. In a case I found these symptoms associated with paralysis of the limbs upon the same side. I concluded, therefore, that the lesion was upon the pons varolii in the origin of the trigeminal, and I concluded so from the fact that there were present the changes in nutrition and sensation which I have just described. The patient died subsequently, and Dr. Edes, of Baltimore, found the lesion at the exact point at which it was thought to be situated. There was no special maturity in making the diagnosis, but I mention the fact simply to show that you may find disease upon one-half of the pons varolii producing upon the same side paralysis of motion and changes affecting the sensation and nutrition of the eye, upon the same side. But disease at the same point can produce just the reverse, and we may have paralysis upon the opposite side, anæsthesia upon the opposite side, and rigidity of the muscles. So you may have paralysis upon the same side with the lesion, or paralysis upon the

opposite side. I will add that you may have motion lessened in that part, with clear symptoms belonging to the trigeminal, without paralysis in the trunk, or in the limbs. There is in this last case, perhaps, some difficulty in the diagnosis. You may think that the trigeminal alone is affected, but it is not necessarily so; for a great part of the pons varolii may be destroyed without producing paralysis, except in the nerves which arise from that region of the brain. Those nerves have been most affected, but in some cases, one especially published by Stanley, a tumor had destroyed one-half of the pons varolii, and there was only incomplete paralysis upon the corresponding side.

The diagnosis in that case would have been clear, from the fact that the trigeminal was affected completely, and the eye was destroyed. There was also present a symptom which is not rare in connection with irritation of the trigeminal, and that is paralysis of the face. There is, therefore, no great difficulty in diagnosis of disease affecting these parts. Another feature you will find very frequently in these cases of disease at the base of the brain. You will find that there is, instead of paralysis of the limbs, anæsthesia or a great deal of hyperæsthesia.

#### ABSENCE OF CONVULSIONS IN DISEASE OF THE PONS VAROLII.

You will also find that there is a remarkable absence of symptoms. The pons varolii has been considered as a part perfectly able to produce convulsions. It is so in animals, and convulsions are readily produced by irritating that part of the brain; but it is not so in man. Disease there produces convulsions less frequently than disease elsewhere in the brain. So if you find that convulsions are not present, and there are symptoms showing that the nerves arising from this part of the brain are affected, you will almost certainly be led to admit that there is disease at that point. There is a part close to the pons varolii which may give rise to most interesting features, and indeed it is not rare that disease in the pons varolii produces some of these symptoms. It is that part which is close to the edge and unites the pons varolii with the cerebellum, the crus cerebellum. When this part is irritated, a rotary movement of the body is produced. It is not special to irritation of that part, however, but irritation of the crus cerebellum and other parts of the brain may produce the same kind of movement.

#### DIAGNOSIS OF DISEASE OF THE CRUS CEREBELLUM.

Diagnosis of disease of the crus cerebellum alone is usually very easy. Hemiplegia depending upon disease of the crus cerebellum may appear upon the same side or upon the opposite side of the body. As a rule, it appears upon the opposite side. But there are two cases out of the entire number, which is not large, of disease of the crus cerebellum, in which paralysis was present upon the same side. The crus cerebellum has been considered as the point of union of those parts of the brain which produce voluntary movements with those parts which produce sensation. So you see that in case of disease of one crus cerebellum you should have always complete paralysis of movement, and complete anæsthesia upon the opposite side of the body. This is absolutely false. Out of some thirteen cases of this kind upon record, complete paralysis is not at all frequent, and cases of complete anæsthesia are very rare—indeed, I know of only two such cases. The facts, then, are not in harmony with the theory that the crus cerebellum is a part containing all the

motor and sensitive fibres going to the opposite side of the body. So little is that true that there are cases in which destruction of the crus cerebellum has occurred without paralysis at all. Certainly, there are ten cases on record in which the entire mass of the crus cerebellum has been destroyed without producing paralysis upon the opposite side, and without producing anaesthesia. I have said that paralysis in some of these cases *seemed* not to exist at all, but it is quite an essential matter that, in the future, more reliable means are employed to ascertain whether paralysis is present or not, than those which are usually employed.

#### PARALYSIS A CONSTANT SYMPTOM OF BRAIN DISEASE.

If you see a man walk about, see that he is able to stand firmly upon his legs, and find that he grasps with both hands firmly, etc., you are at once inclined to think that there is no paralysis. I must say that, although there are many cases of disease of the brain in which there is not marked paralysis, my belief is that, in every form or kind of brain disease, were we in the habit of studying the patient more carefully, we should have a great chance of finding some degree of paralysis.

Most of the instruments employed for this purpose are exceedingly defective.

[A description of an instrument was given. The inventor is one of the Professor's friends. It gives a very clear measure of the strength of the legs, and it can be used to measure the strength of any part of the body.]

I do not think that we can find the exact strength a patient who has brain disease possesses, unless it is measured by some reliable instrument. When I say that sometimes disease almost entirely destroys one corpus cerebellum, or any other part of the brain, without the production of anaesthesia or paralysis, I only mean that so far as the cases have been recorded, no paralysis has been noticed, but I suspect that some degree of paralysis was present.

## Original Communications.

### THE CONTROL OF ZYMOTIC DISEASES BY PROPHYLACTIC TREATMENT.

BY EZRA M. HUNT, M.D.,

METUCHEN, N. J.

A FEW weeks since we had occasion to draw attention to that department of preventive and hygienic treatment which may be designated as *Individual Sanitation*.

We sought to illustrate how many of the zymotic and other diseases are capable of prevention or modification, not only by isolation or outward disinfection, but also by such prophylaxis of the individual as will render him unsusceptible to the contagium, or so little susceptible as to fortify him against its virulency.

While isolation and disinfection of surroundings is important, it is easy to see that a still more radical and valuable method is instituted, if we can fortify the individual against attack. We incline to the belief that in every case where one member of a family is seized with any dangerous zymotic disease, it behooves us to place all those exposed to seizure upon such preventive treatment as has been indicated in a former paper. Since then some new opportunities of trial and test have been afforded by an epidemic of diph-

theria, which, though not very extended, has been of a malignant type.

The first case coming under my observation was that of a lady of twenty, who had the disease in the most aggravated form in which I have ever seen recovery take place. The nurse and younger members of the family were placed upon preventive treatment. One, a servant-boy of thirteen, was overlooked. He alone took the disease, and went to his home near by, in which were five other children. These were at once placed on preventive treatment. Two, being out at work, did not follow out the treatment with that exactness on which we believe the best success depends. These had an exudation and violent fever, which vanished in two days, as when variola shows itself as only varioloid. The rest escaped attack.

In another family of seven, two children were taken on consecutive days, there being four other children in the family. Of these one was sick with remittent fever, and it was not thought best to place him upon preventive treatment. He contracted diphtheria in seven days, and died five days after from its invasion into the trachea. Of those put upon treatment none took the disease save one. She, however, on examination of the tongue, gave evidence that she had failed to follow the treatment. Although of full age, she had defective memory, and it was found that the directions had not been followed. In some other cases, because of no exposed children, or of coincidence of attack, it was not possible to make full trial of prophylaxis. But in these three families I have been greatly confirmed in the opinion that much in the way of limitation or prevention is to be accomplished by precise and regulated sanitation of those exposed.

Why should it not be so? Did not the preparative method for inoculation show how much, by previous dealing with the individual, can be done to make a contagion innocuous?

Most of the contagions are transmitted through the breath, and be they germs or particles, are dependent for their direful success upon a favorable local field for operation. Disease becomes constitutional because at first local, as well as become local because constitutional. If the breath is surcharged with substances or vapors unfriendly to the materies morbi, there is less probability of its successful occupation of the avenues of entrance or the system at large. In some cases the styptic or caustic character of the article used, or the albuminoid coating it affords, interferes with exudation or with that coaptation of plastic secretions, which thus, while thin and soft, are disturbed, before their tenacity or organization is so settled as to be serious. Another class of substances show ability to take possession of organic matter at once, or so to condense or absorb the gases of decay, or so prevent putrefaction or fermentation, as practically to suspend the power of disease toxics. Thus ozone, turpentine, and the permanganates are well authenticated as accelerating oxygenation, and as preventing decomposition, or readily taking possession of the products of decay. If so, there is every encouragement to avail ourselves of them at once, instead of waiting for declarative symptoms. Carbolic acid, salicylic acid, boracic acid, quinine, etc., are unfavorable to germ life, and if this be either the originator or conveyancer of disease, a breath or a system surcharged in advance has hopeful probabilities of resistance.

Still further, Prof. Polli, in his experiments in the treatment of zymotic disease, has found that the bodies of dead animals which have been fed on the sulphites resisted putrefaction much longer than others, and that urine from living animals thus fed remained

fresh, acid, and clear, and free from ammoniacal odor for several summer days. The fact, too, that cotton-wool, carbolized lint, porcelain, etc., do delay or interrupt the passage of disease factors, has some weight in its application to inbreathed air. Although there is need of patient and exact research, we are working in a hopeful field when we seek by precautionary individual treatment to establish resistance, either mechanical, chemical, or vital, to the outside factors of disease. With the mouth, the nostrils, the throat and lungs, the stomach, the salivary and lymphatic glands mildly permeated or wrought upon by such safe yet valuable agencies as have shown ability to meet the contingencies of foreign invasion and morbid changes which are being initiated, we believe the system can generally be fortified against attack, or to such resistance as will avoid danger. Many a disease has the start of us just because the patient has begun to die when the sickness has begun to manifest itself. If only we can preoccupy during the period of attempted and concealed invasion, one ounce of prevention can do greater marvels than one pound of cure.

### A CONTRIBUTION TO THE THERAPEUTICS OF MIGRAINE.

(Read before the Section on Practice of Medicine in the New York Academy of Medicine, Nov. 30, 1877.)

By E. C. SEGUIN, M.D.

PRESIDENT OF THE NEW YORK NEUROLOGICAL SOCIETY.

GENTLEMEN:—The contribution to the therapeutics of migraine which I have the honor to read this evening, will probably strike you as very fragmentary and inconclusive, but I would ask you to consider in a charitable spirit that it is the result of only a few hours' work, and that it is intended as a suggestive rather than a didactic and formal essay.

So short has been the time which has elapsed since I was asked to participate in this evening's work, that I have not been able to collect scattered notes of cases and to make inquiry of former patients; both of which would have been necessary had I wished to base my statements upon statistics. At some future time it may be possible to supply the data upon which the succeeding assertions rest.

Briefly stated, my thesis is THAT BY THE LONG-CONTINUED USE OF CANNABIS INDICA, MIGRAINE OR SICK-HEADACHE MAY BE CURED, MUCH RELIEVED, OR MITIGATED IN SEVERITY.

This idea is not by any means original with me, but was brought out by an English physician, Dr. Richard Greene, who published a short article upon the subject in *The Practitioner*, Vol. IX., p. 267, London, 1872. After reading the article I immediately began using the remedy, cannabis indica, as directed by Dr. Greene, and have continued to do so ever since. My former partner, Prof. William H. Draper, has also used the treatment somewhat during the same period of time; and both of us have been much gratified by the results obtained. I may add, that some inquiry has convinced me that, in this country at least, the article passed unnoticed, and the plan has not been generally tried.

Before proceeding to give details concerning the treatment, it might not be amiss to recapitulate the diagnostic characters of migraine or sick-headache. This affection is essentially neuralgic in its chief manifestation, viz., a severe or excruciating pain in the head and orbit, but not along the superficial branches

of the trigeminus. It affects both sexes, from the age of six or ten years to that of forty or fifty. In some patients it makes its first appearance at puberty, and terminates before the sixtieth year. In females it may, after undergoing aggravation or transformation, cease at the menopause. Very rarely does the disease cease before thirty, and still more rarely does it first appear at that age.

Migraine is pre-eminently an inherited disease, perhaps more directly so than any other neurosis. I possess numerous tables of families in which many members of three generations were affected.

Migraine is periodic in its manifestations, nearly as much so as epilepsy; patients have attacks every two months, or monthly, or every week—seldom several in a week. In some women the periodic return of migraine coincides with menstruation.

An attack of sick-headache usually begins in the very early morning, and lasts all day—seldom longer in uncomplicated cases. In many cases certain premonitory symptoms precede the occurrence of pain. The day or evening before the attack some feel unusually bright and well. At the earliest waking on the day of attack there may be chilliness, or numbness of a limited part of the body, dim vision, colored vision, or hemiopia. These optical disorders are of exceeding interest, and are best observed in those patients whose attacks begin some time after rising. They usually last less than half an hour. Although amblyopia, hemiopia, photopsia are often very serious symptoms, yet in migraine they lose their prognostic significance. In other persons nausea is an early symptom. Pain follows upon the above disturbances and sometimes makes its appearance without them. It is usually in one side of the head, hemicrania; deeply placed "in the brain" or "back of the eye," as patients tell us; it grows in intensity, is sharp, or beating, or pressing, and may reach such a degree of severity that patients strike their heads violently against hard objects, use chloroform, or beg for hypodermic injections of morphia to obtain relief. During the existence of this pain, which may extend to the rest of the head, there is hyperæsthesia of the eye and ear, great irritability, pallor of the face, cool skin, intense nausea, and severe vomiting. So prominent a symptom is vomiting, so early does it appear, and so abundant is the matter ejected, that the sufferers generally, and I regret to say, physicians occasionally consider the headache as caused by "biliousness;" thus reversing the true order of cause and effect. For a while after vomiting there may be some relief to the suffering.

Toward evening the pain diminishes in intensity, changes its character to a dull general headache, and after a night's sleep the patient awakes quite well; in many cases feeling better than before the attack. Sometimes, however, in gouty subjects, or in women at the menopause, headache more or less typical will endure for two or three days.

It should be added that there are cases in which no nausea or vomiting appears; and patients are disposed to separate these from the category of sick-headache, and speak of them as "nervous headaches." I believe that these two varieties are of the same general kind,—of the migraine type.

It would be out of place in this short paper to trace out the varieties and transformations of migraine, and I have only said enough of the symptomatology to make it unmistakably clear what are the cases in which the plan of treatment about to be presented is applicable.

The pathology of migraine is one of the most open questions in medicine, and I can only briefly state my

own opinion, reached by a careful study of physiological considerations and clinical data. I believe, with Anstie and many others, that a lesion (at present undemonstrable) exists or occurs in those parts of the pons and medulla oblongata which give origin to the sensory roots of the trigeminus. Various systemic states, and various irritations from the external world, the abdominal organs, the cerebrum, serve to provoke the attacks.

One very potent exciting cause of attacks is mental overwork or anxiety; another generally recognized is that condition of the system in which oxalate of lime appears abundantly and frequently in the urine, and in which uric acid quickly separates from it—in brief, acidity, or a gouty disposition. Indigestion may also be an exciting cause.

Guided by the above pathological and aetiological notions, I have treated migraine by—

1. Treating the patient, and removing all exciting causes.

2. Treating the attacks themselves.

3. Treating the disease, or the supposed fundamental pathological state in the nervous system.

First.—The treatment of the patient consists in removing all reliable exciting causes, and more especially in correcting acidity. For this purpose I employ the ordinary means, viz., giving nitro-muriatic acid and alkalies, and greatly reducing the saccharine and amylaceous foods of the patient. In cases attended by debility, anæmia, and imperfect nutrition, it may be necessary to resort to tonics, including cod-liver oil.

Second.—Treatment of the attack. The first thing to be done, in my opinion, is to place the patient under circumstances which secure quiet and semi-darkness. The attempt to "fight out" a sick-headache is nearly always vain, and may be injurious. It is better not to allow the patient any food, not even liquids, until toward the close of the attack, or even not till next day; by this, nothing is lost, and much wretchedness is avoided. Ice, or ice washed in brandy, is grateful.

If the patient have a warning (aura of migraine) before nausea or pain, much can, I believe, be done to cut short the attack or diminish its severity by the use of guarana, caffeine, or croton chloral hydrate. In my hands, guarana, or the powder of the seeds of *paullinia sorbilis*, has proved very efficacious. I have prescribed the fluid extract of guarana, Caswell & Hazard's Elixir of Paullinia, the French Paullinia powders, and powdered guarana prepared by our druggists, and all of these preparations have in my hands often cut short or prevented attacks, if given in the early stage of the disorder.

Of the elixir or fluid extract I give a teaspoonful, to be repeated twice, at an interval of an hour. The powders are administered in twenty or thirty grain doses, also repeated every half-hour or hour. I think that I may report that nearly one-half of my patients have derived great relief from some preparation of guarana, and that in several of them attacks have been absolutely prevented, and they have been enabled to go about on the same day.

Caffeine, in doses of two grains, repeated every hour, until three or four doses have been taken, I have lately employed, upon the recommendation of my friend Dr. Geo. M. Beard, and it has appeared to do good.

Croton chloral hydrate, recently recommended in all neuralgic affections of the head and face, I have recently prescribed in doses of 15 and 20 grains, repeated every hour until four doses are taken or relief

obtained. This remedy is to be used more especially in cases where pain is the first symptom, and in other cases if seen when the pain is fully established.

I have no personal experience with the use of large doses of bromide of potassium and of alcoholic stimulants, for the relief of attacks.

Hypodermic injections of morphia and atropia (gr.  $\frac{1}{2}$  to  $\frac{3}{4}$ , and gr.  $\frac{1}{16}$ ) have permanently relieved attacks in a few of my cases; but I am very reluctant to employ this means, so fraught with the danger of the formation of the opium habit. I never allow my patients to take opium or morphia themselves in this disease.

I would add that there is very probably a real ultimate usefulness in shortening or preventing every attack which may threaten to occur during the systematic treatment of the neurosis; we may thus be doing a good deal to interrupt the *morbid habit* which the nervous centres have acquired.

Third.—Treatment of the disease. No treatment of this sort had been tried, to my knowledge, before Dr. Greene made his remarkable researches upon the effect of cannabis indica. Dr. Greene reported cases of many years' standing as having been months and years without attacks while and after taking cannabis indica, and in other extremely bad cases marked reduction in the frequency and severity of the attacks was obtained.

I have said, in the opening page of this small contribution, that I and a few medical friends have used the cannabis treatment ever since Dr. Greene's publication, and with satisfactory results.

The principle of the treatment is to keep the nervous system steadily under a slight influence of cannabis for a long period of time; in other words, we are to employ the "continued dose" of the remedy, as Clarke and Amory say in speaking of the use of bromide of potassium in epilepsy.

I give to adult females one-third of a grain of the alcoholic extract of cannabis indica before each meal, increasing the dose after a few weeks to one-half grain. Males can generally begin with one-half grain, and it is well to give them three-quarters grain in two or three weeks. These doses must be taken with the greatest regularity, just as faithfully and regularly as bromides in epilepsy. Indeed, when beginning such treatment, I usually obtain a promise from the patient that he will regularly take the pills for a period of three months.

As a rule, no appreciable immediate effect is produced by the above doses, though I have known lightness of the head and slight confusion of mind to result from an initial dose of one-half grain three times a day.

Under this apparently and essentially simple plan of treatment, I have known what may be termed excellent results to be obtained. Of course, I do not mean to say that all my patients have been benefited, but, without a statistical table, so difficult to construct from the experience of private practice, I feel certain that about one-half of my cases have been relieved. A few—two or three—after being more than a year without return of their migraine, have passed from under immediate observation. One of these now very rarely has headache, although for several years he has taken no medicine. The majority of patients relieved have obtained months of freedom from attacks while taking the remedy.

I think that we may say of cannabis for migraine that it is nearly as efficacious as the bromides in epilepsy. Both *may* cure, both *do* bring about remarkable interruptions in the series of attacks, both must be employed in the shape of the continued dose.

Cannabis in migraine is less effectual than the bromides in epilepsy, but, on the other hand, it is superior to them in not producing unpleasant or injurious effects.

My friends and former partners, Drs. William H. Draper and Frank P. Kinnicut, have used the above plan of treatment frequently in the last five years, and their results substantially agree with my own.

Some surprise naturally arises upon seeing so much good done by small doses of a neurotic medicine in a disease so deeply rooted as migraine. Our wonder may never cease respecting the *modus agendi* of the drug—its essential potent action; but its gross and practically interesting effect is very analogous to a well-established acquisition of empirical therapeutics. I refer to the successful employment of belladonna or atropia in epilepsy. This treatment, especially vaunted by Trousseau, is by no means useless, although it is no longer fashionable since the more useful bromide treatment has come into general use. I still, however, employ belladonna in epilepsy in conjunction with the bromides, and this combination sometimes brings about gratifying results.

I may be allowed to briefly mention one illustrative case. When Dr. Brown-Séguard went to Europe in 1875 one of his patients came under my care. She had a bad form of epilepsy, and in spite of the most skillful use of the bromides by her illustrious physician she had been having a fit every two weeks for months. I made little change in the amount of bromides she was taking, merely substituting my own simpler solution for Brown-Séguard's mixture, and gave her one-quarter grain of belladonna three times a day—just enough to keep her throat a little dry. From the very beginning of treatment the epileptic attacks became fewer; intervals of one, three, and fourteen months being obtained. In the present year, owing to the uncontrollable cause of the epilepsy, she has had three or four seizures.

A close parallel may, I think, be drawn between the two diseases, epilepsy and migraine; and between the two remedies, belladonna and cannabis; thus, in my opinion, logically fortifying the proposition advanced upon empirical grounds, that cannabis is useful in the treatment of migraine.

1. Migraine and epilepsy are both nervous affections characterized by the occurrence of periodical attacks; the attacks themselves in both diseases are largely made up of vaso-motor disturbances; in both it is probable that the *medulla oblongata* is primarily or secondarily diseased; both affections occur in the same families, and may be present at successive times in the same patient. The late Dr. Anstie has expressed the opinion that the two diseases are akin, and states\* that migraine may develop into genuine epilepsy. I have in my private case-books cases illustrating this proposition, and I am now treating a physician who states that after nocturnal epilepsy appeared, before beginning bromide treatment, his old migraine grew less frequent and less severe.

2. As regards the two remedies, cannabis and belladonna: both are intoxicants and delirians; both dilate the pupil, and it is probable that the action of both upon the central nervous system, when administered in the shape of the continued dose, is very similar.

In conclusion, I would earnestly ask the gentlemen who have honored me with their attention this evening, to give the cannabis treatment of true migraine a critical trial.

\* The Practitioner, Vol. IX., 1872, p. 356.

## Reports of Hospitals.

### ST. FRANCIS' HOSPITAL.

AN INTERESTING CASE OF ACUTE ARTICULAR RHEUMATISM—UNUSUAL NUMBER AND SEVERITY OF COMPLICATIONS.

(Reported by GEO. M. EDEBOHLS, M.D., House-Physician.)

KATE McKAY, æt. 20, single, native of Scotland, domestic, was admitted to St. Francis' Hospital, service of Dr. John H. Ripley, January 19, 1877.

Her family history is unimportant; habits temperate. Has never menstruated, although apparently in the full bloom of womanhood. Up to inception of present illness was never sick in her life, with the exception of some trivial complaint four years ago, which confined her to the house for two or three days. The present attack, attributed by the patient to the influence of cold, began twelve days ago, January 7th. The constant and only symptoms from that date until the day of admission were a moderately severe fever and fugitive pains in various parts of the body, with little evidence of special predilection for the joints.

On admission, complains of severe pain in both knees, which, on examination, however, present nothing abnormal, no swelling, abnormal heat, or redness. Bowels are somewhat loose—five to six passages in twenty-four hours. The tongue is very thickly coated; appetite impaired. Physical examination of the heart and lungs reveals nothing abnormal; respiration, however, is very hurried—forty-two per minute. Pulse 118, small and wiry; morning temperature, 102°; evening temperature, 104½°. Urine acid, with a trace of albumen.

Jan. 21st.—Patient was taken during the night with a sharp, lancinating pain in the right side, much aggravated on deep inspiration. On physical examination, a distinct friction sound is heard over the lower portions of the right lung, anteriorly and posteriorly; there is slight dulness on percussion over the same region anteriorly, and marked dulness, posteriorly, from the ninth rib downward. The needle of a hypodermic syringe was introduced to its full length in this region, and the piston withdrawn. No fluid, however, was obtained until, as the instrument was being slowly drawn out, and but half the length of the needle remained within the chest-wall, a clear serum suddenly rushed in and filled the barrel of the syringe. The explanation was believed to be this: the needle, as it is introduced, traverses successively the chest-wall, the thin layer of fluid contained in the pleural cavity, and the adjoining pulmonary tissue. As long as the point remains in the lung, no fluid can be obtained; when the instrument, however, is withdrawn *slowly*, with its barrel exhausted of air, the fluid will rush in so soon as the point of the needle is again free in the pleural sac. A sudden and rapid jerking out of the instrument, as is often practised, of course will not give the fluid time to enter as the point is traversing it, and negative results are in this way often obtained when the layer of fluid is of only moderate thickness. But to return to the case. The temperature during the day remained steadily at 105°—105½°. Ordered:

B. Tinct. aconiti radic. . . . . gtt. xx.  
Tinct. opii camph., spirit. ætheris nitrosi. . . . . āā ss.  
Liq. ammonii acetat. . . . . v.  
M. ʒ ss. q. 3 h.

Jan. 22d.—Dulness on percussion on the right side extends up to the level of the fourth rib anteriorly, and the angle of the scapula posteriorly. The urgency of the symptoms somewhat diminished as compared with the previous day. Morning temperature,  $102\frac{1}{2}^{\circ}$ . In the afternoon the patient was taken with pain in the left side, of the same character as previously in the right. The intensity of all the symptoms at the same time increased. Respiration, 42; pulse, 110, markedly wiry and small; temperature,  $105\frac{1}{2}^{\circ}$ . On auscultation, a pleuritic friction sound is heard in the left axillary and infrascapular regions. Urticaria wheals have developed over the entire body since the morning visit. Urine contains 10 per cent. of albumen.

Jan. 23d.—The condition of the patient is growing worse; the temperature has risen to  $107\frac{1}{4}$ , and the other symptoms are severe in proportion. In the evening a slight change for the better was noticed.

Jan. 24th.—Physical signs of double pleurisy with effusion. At a point about one inch posterior to left nipple, bronchial breathing, high-pitched inspiration, and a low, creaking friction sound are heard; at no other point are the physical signs of pneumonia present. The patient is greatly prostrated; temperature,  $106\frac{1}{2}^{\circ}$ ; respiration, 48; pulse, 112. The face is flushed; the tongue very thickly coated and greenish-black in the centre. Bowels have continued loose since admission, five or six stools, on the average, in twenty-four hours. Ordered two ten-grain doses of quinine to be taken at 6 P.M. and 8 P.M. respectively; stimulants to be administered freely.

Jan. 25th.—The pleuritic effusion is increasing on both sides, and the patient suffers greatly from dyspnoea. The symptoms are beginning to assume a decidedly typhoid character. The body is covered with clammy perspiration; the lips and teeth are thickly coated with sordes; the sensorium is deeply involved, and the memory failing on minor points. A second attack of urticaria, affecting the entire cutaneous surface, adds greatly to the patient's distress. The secretion of urine is almost entirely suppressed; pulse, 118, and very feeble; respiration, 56; temperature,  $104\frac{1}{2}$ . Ordered, quinine sulph. in divided doses at 2 P.M. and 3 P.M.

Jan. 26th.—The general condition of the patient is slightly improved, but the pleuritic effusion continues to make headway, and she suffers much from dyspnoea. To receive five grains of quinine at 4 P.M. and five grains at 6 P.M. Also, R. Tinct. digitalis  $\text{ʒ}j$ , potassii acetat.  $\text{ʒ}ij$ , aque ad  $\text{ʒ}vi$ . M.  $\text{ʒ}ss$ . q. 3 h.

Jan. 27th.—The dyspnoea was becoming so excessive that preparations were made to evacuate a portion of the fluid in one or both sides of the chest. As she sat up in bed, however, preliminary to the operation, partial relief was obtained by the change of position, and it was thought advisable to defer operation. Auscultatory examination reveals a double pericardial friction sound over the centre of the heart, and a systolic bruit heard most distinctly at the apex. These, together with moderate ascites and slight oedema of the feet, are new features of the case, none of them having been found to exist on a careful examination made twenty-four hours previously. Microscopical examination of the urine reveals the presence of hyaline, epithelial and granular casts. Pulse, 114; respiration, 37; temperature,  $103\frac{1}{2}^{\circ}$ .

Jan. 28th.—The pericardial friction sound is no longer audible; the systolic murmur at the apex is more distinct than yesterday. The pleural exudation is somewhat diminished in quantity, but the ascites

and anasarca have increased. The secretion of urine has again become more free.

Jan. 30th.—General symptoms much improved. The pleuritic exudation is still slowly diminishing; the ascites remains stationary. Two different endocardial murmurs, an aortic systolic and a mitral systolic, are audible to-day. The temperature during the day varied between  $102\frac{1}{2}$  and  $103\frac{1}{4}$ , the lowest average temperature since admission.

Jan. 31st.—The urticaria has reached its fullest development; the temperature has again risen to  $104\frac{1}{4}$ . Severe pain is complained of in the joints of the lower extremities, and on examination both knees and the right ankle are found to be in a state of rheumatic inflammation, and moderately distended by effusion. The breathing is rapid,—forty-eight to the minute—labored and quick; pulse, 120, full and strong. It was determined that the rheumatic element, at any rate, be kept under control; so the following prescription was written:

R. Acid. salicyl. . . . .  $\text{ʒ}ij$ .  
Sodii bicarb. . . . .  $\text{ʒ}iss$ .  
Aque. . . . .  $\text{ʒ}iv$ .  
M.  $\text{ʒ}ss$ . q. 2 h.

Feb. 1st.—There is sensible improvement in the various symptoms, subjective and objective. The patient perspired freely during the night. She complains of cough to-day for the first time during her entire illness. Temperature, A.M.,  $104\frac{1}{4}$ ; P.M.,  $102\frac{1}{2}$ .

Feb. 2d.—A loose, rattling cough is the most annoying symptom to-day. On examination of the chest, this is found to be due to a profuse bronchorrhœa consequent upon a very rapid diminution in the quantity of the pleuritic effusion on either side. The patient suffers no pain anywhere. The tongue is moist and quite clean. No movement of the bowels since yesterday. The urticaria has entirely disappeared. Temperature, A.M.,  $102\frac{1}{2}$ ; P.M.,  $101\frac{3}{4}$ .

Feb. 3d.—The improvement noticed yesterday has been progressive, and the patient to-day feels better than at any time since the beginning of her illness. Temperature, A.M.,  $101\frac{1}{4}$ ; P.M.,  $99\frac{1}{4}$ .

From this day until the patient's discharge from the hospital, the noteworthy occurrences in connection with the case were two slight relapses of the articular affection; a severe cardialgia lasting about a week; and an attack of urticaria affecting the upper extremities. The rheumatic attacks were readily controlled by sodium salicylate; the cardialgia, after having resisted a great variety of remedies, yielded to the application over the præcordia of a plaster prepared by dusting chloral hydrate on the ordinary emplastrum picis Burgundicæ previously spread on a suitable piece of adhesive plaster; the urticaria was of little consequence.

March 15th.—Physical examination of the lungs reveals nothing abnormal. The mitral systolic and aortic systolic murmurs persist, and are the only audible evidences of remaining mischief. The patient left hospital March 19, 1877.

The following are believed to be interesting features in the history of the case:

1st. The successive occurrence within a week's time of acute inflammation of four serous or fibro-serous membranes. The pleuritis of the right side began on the 21st of January; that of the left side on the day following; and the peri- and endocarditis developed January 27th.

2d. The very probable dependence of these inflammatory affections upon the rheumatic diathesis. There was albuminuria, to be sure; but it was regarded as

concomitant upon the general systemic disturbance, rather than as due to chronic structural lesions of the kidneys. A close investigation of the patient's previous history failed to elicit the occurrence at any time of the symptoms usually met with in cases of chronic nephritis; and a careful daily examination of the urine revealed no evidence of albuminuria subsequently to February 10th, or for more than five weeks before leaving hospital.

3d. The complete remission of the joint affection during the period of greatest intensity of the serous inflammations. From January 21st, on which day the pleuritis of the right side began, until January 31st, four days after the incipency of the peri- and endocarditis, the patient never experienced the slightest pain in any part of her body, with the exception of the chest.

4th. The absence of cough as a symptom during the occurrence of so many inflammatory affections within the chest. The patient never coughed until February 3d, two weeks after the beginning of the first pleurisy; and the symptom then appeared to be due to a severe bronchorrhœa consequent upon the rapid absorption of the pleuritic exudation.

5th. The occurrence of three attacks of urticaria within two months. The first two were of a severe character, and general, and apparently contributed largely to increase the general disturbance of the system. The third occurred during convalescence, affected only a small portion of the body, and gave no special annoyance.

6th. The marked change in the character of the symptoms, and the immediate inauguration of convalescence following the administration of the sodium salicylate. The pain and fever speedily subsided; the diarrhœa, obstinate before, was checked; the urticaria vanished; the pleuritic effusion rapidly diminished; the albuminuria became less, and soon entirely disappeared. Query: Were these effects due to the influence of the salicylate upon the rheumatic poison, which was considered to be the main etiological factor in the case?

7th. The complete recovery, in a comparatively short space of time, from the effects of a bilateral pleuritis. The pleural inflammation began January 21st; on March 15th, vesicular respiration was everywhere audible over both lungs, showing that the effused fluid was entirely absorbed.

6. The general rule is never to administer chloroform except during the period of expulsion; but in certain cases of nervousness and extreme agitation it is advantageous not to wait for the complete dilatation of the os.

7. Experience has shown that anesthetics do not arrest the contractions of the uterus or abdominal muscles, but that they weaken the natural resistance of the perineal muscles.

8. The use of anesthetics has no unpleasant effect on the mind of mother or upon the child.

9. In lessening the suffering, anesthetics render a great service to those women who dread the pain; they diminish the chances of the nervous crises which are caused during labor by the excess of suffering; they make the recovery more rapid.

10. They are specially useful to calm the great agitation and cerebral excitement which labor often produces in very nervous women.

11. Their employment is indicated in natural cases until the pains are suspended or retarded by the suffering caused by maladies occurring previous to or during labor, and in those cases where irregular and partial contractions occasion internal and sometimes continuous pain, without causing progress of the labor.

12. In a natural labor, chloroform should never be used without the consent of the woman and her family.

M. Courty advocates the use of chloroform. He thinks it indicated when the pains are very great and irregular, or where the patient demands it.

M. Leblond prefers to use the hydrate of chloral.—*Gazette Medicale*, Oct. 20, 1877.

CEREBRAL THERMOMETRY.—At the meeting of the *Association Française pour l'avancement des Sciences*, on the 30th of August, M. Broca read a paper on "Cerebral Thermometry." He had used six carefully graduated thermometers, one of the sides of the bulb being applied to the skull, while the other side was covered with wool as a protection against atmospheric variations. Two were applied just behind the external orbital apophyses, on each side, two just above the ears, and two over the occiput. With these instruments M. Broca made observations on certain of his *internes* and dressers, who were nearly of the same age, the same intellectual development, and placed in the same circumstances. Each thermometer was left twenty minutes in place. The maximum normal temperature of the brain was found to be 34.85° (94.70° F.) the minimum 32.80 (91.04 F.), the average being 33.82. But there was a marked difference between the two sides of the cerebrum, the average on the right being 33.90 (93.09 F.), whilst on the left it was slightly above 34 (93.20° F.). If, however, the brain work, if it pass from a state of quietude, the two hemispheres become of the same temperature by means of an elevation on the right. After reading ten minutes, moreover, the temperature of the whole brain mounted from the average 33.82 to 34.23°. There was found to be a difference between the lobes, as the following figures show: Occipital lobe, 32.92°; temporal, 33.72°; frontal, 35.28°. M. Broca believes that these observations will be of value in cerebral diagnosis, especially in embolism, as of the left middle cerebral artery, for example, and its partial or complete blockade, whence he thinks there should result a lowering of temperature in the middle lobe, which is deprived of more or less of its vascular supply, and an elevation in the frontal and occipital lobes, to which the blood will be reflected in increased quan-

## Progress of Medical Science.

THE EMPLOYMENT OF ANÆSTHETICS IN LABOR.—M. Piachaud read a paper before the International Medical Congress of Geneva, in which he advanced the following conclusions:

1. The employment of anæsthetics is, as a general rule, advisable in natural labor.

2. The principal substances which have been used for this purpose up to the present time are ether, chloroform, amylene, laudanum, morphia hypodermically, chloral by the mouth and by injection.

3. Of these chloroform seems to be preferable.

4. It should be administered according to the method of Show, that is, in small doses at the beginning of each pain, its administration being suspended during the intervals.

5. It should never be pushed to complete insensibility, but the patient should be held in a state of semi-anæsthesia, so as to produce a diminution of the suffering.

tity. Two cases are mentioned. The observations in one are given. A rheumatic patient is suddenly smitten with hemiplegia and aphasia, and thermometric exploration yields these results: On the left frontal lobe, 35.2°; temporal, 34.3°; occipital, 35.6°. On the right frontal, 34.8°; temporal, 34.8°; occipital, 32.9°.—*Progrès Médical*, Sept., 1877.

**FILARIA SANGUINIS HOMINIS, MATURE FORM.**—After five years' unavailing search for the mature form of the *filaria sanguinis hominis*, T. Lewis, M.B., has at last seen his labors crowned with success. The specimens, two in number, were found in a blood-clot taken from a navoid elephantiasis of the scrotum. Both were injured in the preparation, but enough was left to determine that one belonged to the male and the other to the female sex; one contained ova identical in appearance with the free embryo in the blood and tissues, the other contained a tube resembling the spermatid duct of other nematoid blood-worms. The parasite is of a white color; the cuticle smooth, and devoid of transverse markings, except such as are induced by the contraction of the subjacent muscular walls. The female, when filled with ova, measures transversely  $\frac{1}{16}$  of an inch; the head is slightly club-shaped, and measures  $\frac{1}{16}$  of an inch. The mouth presents no distinctly marked labial subdivisions, nor are any chitinous processes evident. The oral aperture is  $\frac{1}{32}$  of an inch in diameter. The oesophagus is  $\frac{1}{16}$  of an inch in length, without any well-pronounced muscular striae, and shades off gradually into the intestinal tube; the latter measures  $\frac{1}{16}$  of an inch across, and is filled with granular and molecular matter. The width of the parasite immediately below the cephalic extremity is  $\frac{1}{16}$  of an inch; at junction of oesophagus and intestine  $\frac{1}{16}$  of an inch; half an inch lower  $\frac{1}{16}$  of an inch. The ova are enveloped by a delicate pellicle, but possess no distinct shell; their shape depends on the degree of surrounding pressure, and when mature they measure about  $\frac{1}{16}$  of an inch in diameter. Mr. Lewis has not seen any indication of reproductive organs, or even any well-defined intestinal tract in the ova he has examined, and agrees with the opinion maintained by Leuckart with regard to embryo-hæmatozoa generally, that they do not advance in development so long as they remain in the blood.—*The Lancet*, Sept. 29, 1877.

**HYDROPATHY AND SYPHILIS.**—P. A. Levin (*Eira*, Bd. 1, H. 1) does not claim that hydropathy can replace mercury or iodine preparations in the treatment of syphilis, though he thinks it may often render great assistance when combined with these remedies. The cold and hot water treatment both promote the vital phenomena of that important organ, the skin, and one or the other should always be used, especially when inunctions are employed. The cold water increases the tone of the skin, and thus promotes absorption, while the warm bath increases the excretion through the skin. With the former, therefore, the quantity of ointment rubbed in is utilized to a greater extent than with the latter. This is also shown by the fact that with the simultaneous use of the warm bath, as at Aix, a proportionately greater dose may be used in inunctions without danger than when the cold bath is used. Dr. L. for more than twenty years has used the inunction treatment simultaneously with cold baths and douches, and he has found that he could not apply the gray salve in such large doses without being obliged to suspend the treatment occasionally. In prescribing the various forms of baths, close attention should be paid to the age, condition, and habits of the patient. Cold water is best for

young, strong individuals; warm water for older people. Those who are naturally weak or relaxed, or have become so by the improper use of mercury or iodine, should commence with a warm-water treatment, and close with the more or less prolonged use of cold. The cold-water treatment is exceedingly useful for those who are in the chlorotic condition often developed during the repeated outbreaks of syphilis, or in consequence of badly conducted mercurial medication. This is especially true of young persons, but this treatment will often prove useful in those beyond middle age. The greater the age, however, the shorter the treatment, for though the strength at first increases, it is followed later by depression. The water-cure is hurtful in general marasmus. The author has treated several mild cases by the water-cure alone, and though relapses did not occur, we must still bear in mind that some cases get well without any treatment.—*Nordiskt. Med. Archiv*, Bd. 9, H. 2, 1877.

**TENSION OF THE BLOOD IN EPILEPTIC SEIZURES.**—Magnan produced artificial attacks of epilepsy in dogs by injecting the essence of absinthe into the veins, and he then found that in the tonic period of the epileptic seizure arterial tension increased, and the semi-tetanzed heart beat with greater frequency. In the clonic period the cardiac pulsations became slower, but afterwards resumed their normal rhythm. These two opposite conditions of the heart cause the admission of two different mechanisms in explaining death occurring during an attack. If death occurs during the tonic period, the cause is cardiac tetanus, which suspends the circulation; if during the clonic period, it is syncope, which produces the same result.—*Lo Spalanzani and Gazz. Med. Ital. Lomb.*, No. 40, 1877.

**CASES OF INTESTINAL OBSTRUCTION, WITH REMARKS ON DIAGNOSIS AND TREATMENT.** By Sidney Coupland, M.D., and Henry Morris, M.A., M.B.—This paper was based upon an analysis of the cases reported in the records of Middlesex Hospital, and in the Transactions of the Pathological Society, during a period of over thirty years. Alluding to the tendency of fecal accumulations to set up internal inflammation, and even ulceration, they showed that the cæcum is the point of greatest danger, owing to its peculiar position, receiving the influx from the ileum and the reflux from the strictured gut. On this account, therefore, they strongly advise the performance of right colotomy as soon as the diagnosis of stricture is established, thus affording immediate relief to the over-distended cæcum. In cases where the disease is situated above the cæcal valve, they recommend enterotomy as a safer, and a far more effectual means of affording relief to the distended bowel, than acupuncture. In reviewing our means of diagnosing the seat of stricture, they conclude that when it is above the reach of physical examination, it is necessary to study our statistics of such cases. As, however, the stricture is most frequently in the large intestine, an error as to the precise seat would not affect the operation they recommend.—*British Medical Journal*, Sept. 1, 1877.

**WARREN PRIZE.**—This prize of the present year has been awarded to E. O. Shakespeare, M.D., of Philadelphia, for an essay on the Healing of Arteries after Ligation. The subject for 1880 will be Original Observations in Physiology, Surgery, and Pathological Anatomy. Essays should be forwarded to the resident physician, Massachusetts General Hospital, Boston, on or before February 1, 1880. The amount of the prize will be \$400.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

## MEDICAL CERTIFICATES IN THE DAILY PAPERS.

It has often been said that it is a reflection upon the medical profession to have a Code of Ethics; that the very existence of such a set of laws implies a temptation for wrong-doing, and a consequent necessity for discipline. Every medical man is forced to admit the truth of this, but he has some comfort in the thought that to err is human.

The medical, as far as the Code is concerned, is different from any other equally liberal profession. In no other calling is there any system of laws by which the actions of the individual members are governed. This does not, however, prove that there is less necessity for standard rules of conduct and of government either in the clerical or legal profession, but that the profession of medicine is in advance of the others, and is more zealous in preserving its dignity, in developing its own resources, in protecting the rights of its individual members, and in enlarging its sphere of usefulness. The proposition so often made, to dispense with the Code, is certainly far from a reasonable one. The more we see of medical men in their relations to each other and to their profession, the more we are convinced of the necessity of some definite rules to govern their conduct. This is especially so of late years, and the conclusion seems almost irresistible that the moral tone of the profession has very much lowered in that time. To what particular cause this may be due, we are at a loss to determine. We wish barely to allude, in this connection, to the fact that very many of our leading men are doing boldly what they would not think of doing a few years ago. The illustration in point which will occur to every reader is the very objectionable and shameful parade in the daily papers of medical certificates in the advertisements of certain mineral waters. If their example is to be followed, and a new fashion instituted, the dignity and influence of medicine will be at an end, and the

public will have no means of distinguishing those whom we would gladly honor, from the unprincipled quacks, whose only concern is to be kept in public view.

Advertising of any and every sort is very properly condemned by the profession. The reason for this is obvious, in that it allows a few to take advantage of the many. There is no intention of preventing physicians from holding intercourse with the public as teachers. In that capacity they can speak for their profession, and help to maintain its dignity, honor, and usefulness; but as soon as they place themselves before the public as practitioners, that moment they lay themselves open to the charge of advertising. It is certainly not educating the public, to certify to the fact that Appolinaris water is "a delightful beverage," or is "far superior to Vichy, Seltzer, or any other;" or "is most grateful and refreshing;" or "is useful and very agreeable;" or "healthful and well suited for dyspepsia;" or "by far the most agreeable alone or mixed with wine, and useful in catarrhs of the stomach or bladder, or in gout;" or "well suited for dyspepsia and cases of acute disease;" or lastly, "is not only a luxury, but a necessity." And yet these very remarkable certificates, with the names and addresses of the writers, appear in the papers all over the country without any open protest being made against it. If these gentlemen are thus doing their duty or elevating their profession in the eyes of the public—educating the people to a proper appreciation of the dignity of a noble calling and the value of medical certificates—it is time that a new Code should be made. As we have previously remarked, the profession is much interested concerning the abstract justice of this method of advertising. There is not so much concern in regard to the individuals, as to the principle of which they are seemingly the willing exponents. If the transgression was made by ordinary medical men, charges would have been preferred; they would be branded as advertisers, their names be omitted from the *Medical Register*, and if non-repentant after a reprimand, they would probably be expelled from their County Society.

Again, in the advertisement of another mineral water—the Hunyadi János—medical certificates from the same gentlemen appear. In reading them, one can hardly escape the conviction that no other laxative should be used; so agreeable, painless and certain is it; in fact, that it is the only one specially "adapted for daily use." Who, now, can blame any reader of a daily paper if he quotes the highest medical authority to prove that this mineral water is better than anything else? Certainly, if these certificates were written to order, they could not help the sale of these proprietary waters more effectually. But the question is not how much of these waters may or may not be sold, but how far is it proper for medical men to publicly recommend their use, as in dyspepsia, catarrhs of

the bladder and stomach, in gout, etc. ? At best, this is cheapening medical advice by offering it gratis, by placing a premium on self-medication, by encouraging indiscriminate prescribing, and by lowering the tone and dignity of the profession generally. If these certificates were for circulation among medical practitioners, they would be taken at their real value ; but, paraded before the public, they are apt to mislead, and create misapprehension as to the legitimate resources of our materia medica. If there is any excuse for an error in judgment in giving the certificates, there is certainly none for allowing the daily advertisement of their names as medical practitioners in the different daily papers. It is somewhat astonishing, knowing, as they must, that their course was not indorsed by their brethren, these gentlemen should not long ago have withdrawn permission to use their names in any and every daily paper, and thus have vindicated the true dignity and higher instincts of a time-honored profession. But as their case now stands, they have not only failed to do so for many months, but the continual appearance of their names in the public advertisements would seem to defy that discipline which with lesser men would have been swift and certain.

We repeat that the profession is very much interested in this question, and would like to see it settled one way or the other. We have on a previous occasion brought it to the notice of the County Society, and now that its new Committee of Ethics has been appointed, may we not hope that some authoritative decision will be rendered ?

#### THE ENLARGEMENT OF THE MEDICAL RECORD.

WITH the commencement of the coming year, the MEDICAL RECORD will be enlarged by four pages of reading matter in each number. This increase seems to be warranted, not only on account of the expansion of the subscription list, but of the extra number of advertising sheets which have been added to the journal. We shall thus be enabled to give to our readers over two hundred pages in the year more than they have been accustomed to receive, and without extra expense to them. With the increased facilities which these additional pages will afford, we hope to make the RECORD more and more interesting and useful to the general practitioner.

**WORMS IN THE HEART.**—There has been an alarming epidemic among dogs in China, due to worms in the heart cavities. The left ventricle has been found frequently filled with them. As long as they stay there the animal is considered safe. No cause has been assigned. A very beautiful specimen of this condition is in the museum of the College of Physicians and Surgeons of this city. The heart was sent to the institution from China by a medical missionary and an alumnus.

**CLEANING THE STREETS.**—A conference of the heads of several municipal departments met on Tuesday to consider the street-cleaning question, but no conclusion was arrived at.

## Reviews and Notices of Books.

### AIKEN, S. C., AS A HEALTH STATION.

IN a short pamphlet on Aiken (S. C.) as a Health Station, Dr. N. H. Geddings offers a contribution to medical climatology, which, while primarily directed to the purpose of enumerating the advantages of Aiken as a resort for invalids, contains a valuable collation of the climatological statistics of health resorts. The two principal points discussed by Dr. Geddings are temperature and relative humidity, adopting, as concerns the latter, the convenient classification of Vivenot, who denotes atmospheric saturation by 100 per cent., half saturation by 50, and so on, the figures representing the percentage of relative humidity. Vivenot classifies climates where the air contains only from 1 to 55 of moisture as excessively dry ; from 55 to 70 as moderately dry ; 71 to 85 as moist, and 86 to saturation (100) as excessively moist. As compared with the famous health resorts of the world, the relative humidity of Aiken is only 64.04, while that of St. Remo is 65, Mentone 70, Nice 71, Hyères 58, Cannes 62, Palermo 73, Madeira 73.9, Riviera da Pouente 70. The mean annual temperature of Aiken is 62.70, the mean summer temperature, 75 ; the mean for the spring months, 55 ; that of the autumnal, 71° ; the winter mean being 48.55. The author recommends the resort for malarial diseases, gastric catarrh, convalescents from pneumonia and pleuritis, from typhoid fever, syphilis, scarlatina, and whooping-cough, and for scrofulous patients ; but not for laryngeal consumption, laryngitis, Bright's disease, eye diseases, or diseases of the nervous system.

### NEW YORK ACADEMY OF MEDICINE.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

*Stated Meeting, Nov. 20, 1877.*

DR. GOUVERNEUR M. SMITH, CHAIRMAN.

#### THE THERAPEUTICS OF MIGRAINE.

DR. E. C. SEGUN read a concise paper upon the above subject (see p. 774). It being before the Section for discussion :

DR. A. McLANE HAMILTON remarked that he had given the cannabis indica a fair trial in the treatment of migraine, and had been very much pleased with the results obtained. He was of the opinion, however, that there was an element in each case to be considered before administering any medicine to relieve or remove the paroxysm. He fully agreed with Anstie, who regarded migraine as but the primary step which ended in some more extended process affecting the nervous system. It was a condition which was essentially one of lowered vitality. Migraine as well as other forms of neuralgia were very common during such times as the general system was very much depressed, and when the processes of nutrition were taxed severely ; for example, at and immediately following the time at which puberty was reached. It was believed to be the most important indication in treatment to build up the general system. Dr. Hamilton had of late tried Dr. Weir Mitchell's rest-treatment with great success.

For the relief of the paroxysm he favored the use of diffusible stimulants; such as some preparation of ammonia, aromatic spirits in free doses, or muriate of ammonia in doses of 20 to 30 grains. Paullinia might be used, and last but not least, he had used, with very good results, the galvanic current from 15 or 20 cells. That which should be borne in mind, however, was to treat the condition that gave rise to the neuralgia, and fortify the patient by supporting the general strength.

DR. G. M. BEARD remarked that he read the article on the use of cannabis indica in the treatment of migraine when it first appeared in the *Practitioner*, and then resolved to devote himself to experimenting with it for the purpose of determining, if possible, its exact value. He soon had occasion to prescribe for a case of sick-headache, and directed that the patient should take the cannabis indica in one-third grain doses. The case was an obstinate one, and the doctor soon lost sight of it, and at the same time lost his enthusiasm regarding the value of the remedy.

Another reason why he lost his enthusiasm was, because he had been using tonic treatment, mainly central galvanization, but associated with some other remedies, and had realized many good results. It had been his experience also to see very decided and permanently beneficial results follow change in occupation. A trip to Europe for three months might break up the tendency towards having these attacks. It was thought that the tendency of sick-headache was to pass into other forms of nervous disease, or to break up. That might occur at any period of life.

With regard to the treatment of the attack he had had the most satisfactory results from the use of caffeine and muriate of ammonia. Either the citrate or valerianate of caffeine might be employed and administered in two-grain doses at any stage of the attack. The exact size of the dose he had not fully decided upon, but probably a dose of two grains could be taken, and with safety be repeated in twenty minutes.

Dr. Beard thought it hardly true that sick-headache usually came on in the morning, but that it might appear at any time during the day or even in the evening. There were many who woke up in the morning with the headache, but there were many others in whom the attacks appeared in the middle of the forenoon, or in the middle of the afternoon.

A great advantage attending the use of caffeine was the fact that it could be carried and taken by the patient without inconvenience when the headache began to manifest itself. Next to caffeine, Dr. Beard ranked muriate of ammonia in very large doses freely diluted with water. With these two remedies he thought four out of five attacks could be broken up.

With reference to the relation between sick-headache and other nervous diseases, Dr. Beard's views were not exactly in accord with those presented by the author of the paper. He did not think there was any constant relation between migraine and epilepsy, for he had records of fifty cases of migraine without epilepsy. The doctor also believed there were various gradations and shadings of sick-headache which should be considered; all dependent, however, upon the pathology described.

DR. HUBBARD had used paullinia both with and without success.

DR. CHEESMAN remarked that in his family sick-headache had been very common, but that none of the members had ever had epilepsy.

DR. SELL believed that there was a great variety of this disorder, and that each case required its own

special treatment. In cases characterized by vomiting he had succeeded in removing the symptoms by the use of paullinia, or bicarbonate of soda with hydrastis canadensis. In the neuralgic form, especially the dental, the hydrate of chloral had served him best. In the melancholic variety, the cannabis indica was indicated, and it might be beneficially modified by being combined with hyoscyamus. For those who suffered from coldness during the attack there was nothing better than nitrite of amyl.

DR. HAMILTON had tried chloral hydrate, and had not found it serviceable in any form of the disease.

In the morning cases he had succeeded not unfrequently in mitigating, if not removing, the symptoms by having the patient take a cup of strong coffee or tea before rising.

DR. BEARD referred to a cause very commonly overlooked, namely, excitement or irritation of the genital organs, sometimes so trifling as scarcely to attract the attention of the patient.

On motion the paper was referred to the Academy, and the Section adjourned.

## New Instrument.

### A NEW OPEN-EYED NEEDLE.

ONE of the petty annoyances of a protracted surgical operation is the necessity for threading needles. The quicker and easier this latter is done, the better. In order to give some aid in this direction, I have devised a needle represented in the accompanying cut.

As will be seen, the eye is open, but in a peculiar way, which admits of a loop of thread being easily inserted, at the same time there is little if any danger of its slipping out. Another advantage consists in the projecting shoulder on the front of the eye, which effectually prevents any catching or tearing of the tissues as the needle is drawn through. In my hands it has served every purpose.

GEO. F. SHRADY.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from November 25 to December 1, 1877.*

ALEXANDER, R. H., Major and Surgeon. When relieved from duty as Post-Surgeon, Fort Vancouver, W. T., to comply with par. 2, S. O. 220, A. G. O., C. S. S. O. 167, Dept. of the Columbia, Nov. 13, 1877.

ALEXANDER, C. T., Major and Surgeon. Assigned to duty as Post-Surgeon at Fort Vancouver, W. T. S. O. 167, C. S., Dept. of the Columbia.

NORSON, W. M., Major and Surgeon. Assigned to duty at Fort McKinney, Wyo. T. S. O. 135, Dept. of the Platte, Nov. 24, 1877.

COWDREY, S. G., Capt. and Asst. Surgeon. Assigned to duty at Fort Cameron, U. T. S. O. 135, C. S., Dept. of the Platte.

## Medical Items and News.

**CONTAGIOUS DISEASES.**—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending December 1, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
Nov. 24.....	0	12	68	3	29	79	0
Dec. 1.....	0	18	63	2	29	54	0

**LOCALIZATION IN CEREBRAL AND SPINAL DISEASES.**—Prof. E. C. Seguin will deliver a course of lectures upon the above subject at the College of Physicians and Surgeons, during December and January, Thursdays, at 4 P.M., beginning Dec. 13th.

**EXTIRPATION OF THE PREGNANT UTERUS OF THE CAT—RECOVERY OF PATIENT.**—Prof. John C. Dalton has lately performed, in a highly successful manner, a very interesting operation upon a pregnant cat. The animal having been sent to him when on the eve of parturition, he anesthetized it and made a free incision through the abdominal walls with the idea of making the Caesarian section upon it. When the gravid uterus had been exposed, however, it looked so very inviting that he could not resist the temptation to remove the organ entire with all its contents. This accordingly was done, and all hemorrhage having been efficiently controlled, the external wound was sewed up, and the animal permitted to go in peace. When the uterus was removed from the body an incision was made through its walls and one of the litter of kittens was extracted, while its companions were permitted to remain *in statu quo*. After placing the youthful scion of the feline race in cotton-wool near the fire, Dr. Dalton left the room for a considerable time, and when he returned, what was his surprise to find it meandering about the floor, evidently in search of something wherewith to satisfy the cravings of a newly-developed appetite. Not having a foster-mother for it convenient, however, and also probably being of the opinion that New York was already sufficiently supplied with members of its species, he concluded that he would let it depart this life at an early period in its career; and, accordingly, its existence here was but a very transitory one. The maternal cat, notwithstanding the severe shock to her system, made an excellent recovery, and is now said to be as well as ever. If Dr. Dalton were to repeat any such operations upon the human subject, and with like success, he would soon be as widely known as an obstetric and gynecological surgeon as he long has been as a physiologist.

**A LARGE OYSTER STEW.**—If oysters are really serviceable as brain-food, there was probably a remarkable development of cerebral structure among some of the inmates of the hospitals and other public institutions of this city last week. Between fifty and sixty thousand oysters are said to have been put at the disposal of the Commissioners of Charities and Correction for Thanksgiving Day, and they were accordingly distributed by them among the various institutions. Some nine thousand five hundred fell to the share of Bellevue Hospital, and these were served up for supper in

the form of one enormous stew; which the warden, Mr. O'Rourke, is no doubt right in claiming as by all odds the largest stew on record.

**DR. JAMES T. WHITTAKER**, late editor of the *Ohio Clinic*, and Professor of Physiology in the Medical College of Ohio, was on a short visit to this city, and was the recipient of the hospitalities of several prominent physicians here.

**PHYSICIAN-DEPUTIES.**—Among the Deputies elected to the Corps Legislatif at the late election in France, there are thirty-five physicians. In two departments in which medical men ran, second ballots had to be held, of the results of which we have not yet been informed. Thirty-four of the thirty-five were re-elected to fill seats that they had occupied in the last Assembly. Five physicians, who were candidates for re-election, were defeated. All of those elected are Republicans, with two exceptions; of these two, one is a Legitimist, and the other, Baron Larrey, is a Bonapartist.

**PROF. CONNER**, of the Medical College of Ohio, has been tendered, and accepted, the Chair of Surgery in the Dartmouth Medical School, at Hanover, N. H., made vacant by the death of Prof. A. B. Crosby.

**PRUSSIAN SURGEONS IN ROUMANIA.**—At the request of the Princess of Wied, the mother of the Princess of Roumania, leave of absence for three months was granted some time ago to a number of Prussian army surgeons who wished to go to Bucharest. They have as yet, however, been unable to obtain admission to the army hospitals in that city, it is said, because the chief surgeon, who is a Frenchman, refuses to accept their proffered aid. They were asked to go to the front with the troops, and would probably have consented if they had been allowed to rank with the Russian army surgeons. It is probable that they will soon return to Germany, as there does not seem to be any likelihood that they will be able to turn their leave of absence to any further use.

**PHILADELPHIA HOSPITAL, PHILADELPHIA.**—Prof. Louis H. Duhring has been appointed dermatologist to the Philadelphia Hospital.

**MAXIMS OF SUCCESS.**—Dr. James Syme used to give his students the following rules to insure success in practice: 1. Never look surprised at anything. 2. Before stating your opinion of a case on your second visit, ascertain whether your previous directions have been complied with. 3. Never ask the same question twice.

**LARGE STONE.**—Prof. Gross, of Philadelphia, operated recently by the lateral method, removing from a boy aged 12 years, a stone which weighed one ounce and five and three-quarter drachms.

**ABUSE OF MEDICAL CHARITIES.**—The *Boston Medical and Surgical Journal* misunderstands us when it implies that for the sake of remedying the abuse of medical charities, that we are in favor of closing dispensaries and out door departments. We are, however, only in favor of decreasing their number to a decent standard, and then managing them in the interests of the deserving poor, rather than for the benefit of the medical schools in want of clinical material.

**FRAUDULENT LENSES.**—A decided impression has been created in scientific circles in this city, by the discovery that one of our most noted opticians is in the habit of importing from Paris ordinary commercial lenses, remounting them after the English style, and

palming off such inferior productions as lenses of the best makers. The fraud was discovered by one of our microscopic experts, who was called in to evaluate the stand, lenses, and other microscopic appliances, left at the death of a physician of considerable prominence in this city. The stand had the name of a prominent manufacturer. The lenses, supplied by the same house, were duly labelled with the name of a celebrated maker, but, on testing, did not yield the results of genuine Wales glasses. Closer inspection, guided by the peculiar color of the field, when used with a student's lamp burning kerosene, led the expert to suspect that he was dealing with objectives manufactured in Paris, it being a fact familiar to experts that objectives of Vienna, Berlin, Paris, London, or American manufacture, have each their own peculiarities as concerns the tint of the field, by which they can be identified with tolerable certainty. Subsequent inquiry established the fact, that our expert was correct in his induction, and eventuated in the exposure of a fraudulent practice, that has probably been carried out by American opticians for a long time.

**A SUBSTITUTE FOR THE WEBER NASAL DOUCHE.**—A strong argument against the general usefulness of Weber's nasal douche is pointed out by Dr. Rumbold, of St. Louis, who has studied the subject by both ante- and post-mortem experiments. He found that the superior and posterior portions of the nasal and nasopharyngeal cavities are never reached by the irrigating fluid, which never rises to a higher level than the lower border of the posterior nasal opening. At the autopsy of a patient who had used the douche for about three months, the last time only about six hours before death, the posterior portion of the superior half of the nasal cavities was found to be incrustated with old and offensive secretions. After observing the inadequacy of the Weber nasal douche, Dr. Rumbold devised an apparatus, which he calls the catheter nasal douche. It consists of a spray-producing apparatus, and a flexible catheter about six inches long, closed at the distal end, and perforated by five small openings three-eighths of an inch apart. This is introduced along the floor of the nose, the openings looking upward, and a coarse spray is thrown out, which, it is claimed, will reach every portion of the irregular surface of the cavity, and make a perfectly efficient and direct local application. The irrigating solution consists of warm salt and water, with the addition of five grains of salicylic acid to the pint, when the secretions are offensive.—*Chir. Med. Jour., and Exam.*, August, 1877.

**BACTERIA AND ECZEMA.**—It is getting to be an even race between eczema and bacteria. Eczema was a liberty or so ahead at the first of the year, but Lister's fresh start in London has brought the other horse within a few book-shelves of the skin men's entry. By the shades of John Hunter! another description of the germ theory and the antiseptic method pointed at this Othello's breast, and he retires from business.—*Louisville Medical News*.

**LINHART.**—Dr. Wenzel v. Linhart, the Professor of Didactic and Clinical Surgery in the University of Würzburg, Bavaria, died on the 22d of last October. He was born in 1821, and studied in Vienna, where he was a pupil of Dumreicher. He subsequently became a tutor in the University of Vienna, and in 1856 was called to Würzburg. While still young, he made a name for himself, as an able writer and a skilful operator. He was the author of a work on Operative Surgery, which passed through many editions. He filled

the chair of Surgery in Würzburg for over twenty years, and during this period his reputation as an operator of rare skill became world-wide. It is reported that Richard Volkmann will receive the call to Würzburg as his successor.

**NUMBER OF TEACHERS IN THE PRUSSIAN UNIVERSITIES.**—According to the official figures, the number of teachers in the nine Prussian Universities, the Academy of Münster, and the Lyceum of Brunswick, during the last summer session, was 906. Of these 470 were regular professors, 7 were honorary professors, 202 were assistant professors, and 227 were private tutors. The Protestant theological faculties counted 86 members, the Catholic theological 24, the legal 89, the medical 254, and the philosophical 403. In the University of Berlin alone there were 201 teachers: 63 regular and 57 assistant professors, and 77 private tutors.

**HEALTH OF THE KARS GARRISON.**—Advices from Kars up to September 15th, state that an epidemic of dysentery broke out among the troops of the garrison during the first half of the month. Typhoid fever remained, however, the predominant disease. Unfortunately the contracts of the majority of the physicians, who had been employed by the Porte, had expired previous to the outbreak of the epidemic, and had not been renewed. The consequence was a dearth of medical men, which was severely felt as the number of sick increased.

**INOCULATIONS OF HORSE-POX,** recently performed in the École vétérinaire of Lyons, produced magnificent cow-pox pustules on cows and also on asses.

**PREVALENCE OF BRIGHT'S DISEASE AND ITS DISCOVERY IN APPARENTLY HEALTHY SUBJECTS.**—At a recent meeting of the Kings Co. Medical Society (N. Y.) B. A. Segur, M.D., read an exhaustive paper on the "Prevalence of Bright's Disease and its Discovery in apparently Healthy Subjects," which will bear a very careful perusal, but, consisting in the main of statistics, cannot be condensed. His two conclusions of practical value are, that a large proportion of deaths, recorded under the names of pneumonia, pleurisy, pericarditis, apoplexy, convulsions, diarrhœa, etc., have Bright's disease for their predisposing cause, and that, while the appearance of albumen in the urine marks an advanced stage of kidney degeneration, the hyaline cast is a very early and important means of diagnosis, as significant in its relation to the kidney as the mucous râle is in its relation to the lung.

**CREMATION IN SWITZERLAND.**—The Cremation Society of Zurich has just succeeded in obtaining from the Government permission to practise cremation in the new cemetery in that town. There are certain conditions connected with this permission: 1. Siemens's apparatus, or some improvement of it, must be used. 2. The deceased must have given information of his or her desire to be cremated, by a written, officially certified declaration, made while of sound mind. 3. The body must be carefully examined by the district physician, and as a rule an autopsy must be held, to exclude the possibility of a violent death. 4. Permission for the cremation in each individual case will be obtained from the Prefect of Police, after Sections 2 and 3 have been complied with. 5. The process of cremation must be conducted in such a way as not to interfere with the religious rites of the sect to which the deceased belonged.

**DR. ABEL LAFLAIRE,** the surgeon-in-chief of the Hospital of Beaune, died recently, at the age of 52 years.

### CHOREA: ITS ETIOLOGY AND VARIETIES, WITH A NEW TREATMENT.

A CLINICAL LECTURE DELIVERED

By PROF. HORATIO C. WOOD, JR., M.D.,

AT THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

(Reported for THE MEDICAL RECORD.)

I BRING before you to-day a case of true hysterical chorea. This woman, ten months ago, had a severe fit, during which she lost all consciousness. Since that time she has suffered from crying spells and constant jerking movements. The movements came on all at once. They have affected her speech, but not her deglutition. She has always slept well, and has had no jerking movements in her sleep. Early in the history of the case one side of her body was entirely paralyzed. There is no palsy at present, however. I can find no adequate cause for the attack. The patient never had a quarrel, was never hurt, and never severely frightened. She has complained frequently of late of the "globus hystericus."

In diagnosticating, the distinction must be drawn carefully between chorea proper and the so-called choreic movements. Hammond's chapter on chorea, in his excellent treatise on "Nervous Diseases," is chaotic. He has confused chorea proper with choreic movements and the *chorea major* of the Germans. These choreic movements must be distinguished from tremors. Tremors are entirely different in appearance from voluntary action; they are tremblings or vibrations of a part, and are of two kinds, constant and occasional. This latter form always attends the attempt to make a movement. Choreic movements are irregular, convulsive actions of voluntary muscles, and often simulate voluntary movements. They are either entirely withdrawn from the sphere of volition, or but little under its control. These movements are of a chronic kind. They may be excited by any attempt at voluntary movement. Not every case of choreic movement is one of chorea. The local choreas are choreic movements, definite spasms located in one part, but not true chorea. Twitchings on one side of the head and face is an example of a local chorea. The local choreas, or choreic movements, are usually incurable. *Chorea major* has no relation with the *chorea minor* of the Germans, or what I really term *true chorea*. *Chorea major* consists of a series of complicated movements occurring at irregular intervals and exactly simulating voluntary acts. Among these may be mentioned the *subacute* form, in which the patient takes three steps forward and then makes a low bow. This is the result of an entirely uncontrollable impulse. In another form the patient will rise, jump over his chair, and then sit down again as if nothing had happened, or he will rise and run rapidly around the room and then sit down again. I know of one gentleman who is subject to just such attacks of these. Strange to say, he is entirely free from them when he is travelling. These so-called choreas are very rare.

In Europe there have been regular epidemics of what has been described as chorea, at different times. These epidemics have been largely hysterical in their nature, and very often connected with religious excitement. They were most frequent in the middle ages; the so-called "tanzwuth" of central Europe is

an example. The entire population of a town would be seized with a "dancing mania." Then there were the "convulsionnaires du Saint-Médard," who had to be absolutely thrown down and trampled upon before the spasms could be stopped. "Tarantulum" of Italy is another instance of the same sort of disease. In this disorder the victims were supposed to have been bitten by a large spider, a species of tarantula, and danced and whirled until they were put to rest by the sound of music, or the total exhaustion of nature. Under the influence of these hysterical epidemics of chorea the strength was enormously increased for the time being, so that weak, frail women had to be beaten with iron bars to bring them out of the controlling influence of the supposed demon. The late "shouting mania," which some years ago broke out in Kentucky among the Presbyterians first, I believe, and then spread to the Baptists and Methodists, is another instance of a widespread hysterical disorder which is often confounded with true chorea (the *chorea minor* of the Germans).

The diagnosis of true chorea is rendered easy by reason of the peculiar jerking movements pathognomonic of the disorder. In the United States, chorea is met with most frequently in the spring of the year, and is usually associated with a depressed state of the nervous system. It is easy to see why it should occur in the spring. The cold weather, privations, and discomforts of the winters in our large cities have a peculiar tendency to pull down the nervous system. "Spring fever" is the visible exponent of this general relaxation and lack of tone. Chorea, too, is a frequent sequela of rheumatic attacks, and rheumatism is, of course, most prevalent in the late winter months.

Complicating chorea there is very often found a functional or organic cardiac murmur. The great difficulty lies in the inability to determine whether the cardiac murmur in choreic children be functional or organic. The cause of this functional murmur lies in the involvement of the valves and muscles of the heart in the choreic movements. The murmur may possibly be anæmic in its nature.

The pathology of chorea is exceedingly obscure. I doubt whether any fixed organic change can be found after death. Some pathologists refer the peculiar symptoms of the disease to the stoppage, by emboli, of the minute arteries of the corpora striata and of the cord. Ninety-nine out of a hundred cases of *chorea minor* are completely cured. This would not be the case if so serious an organic lesion lay at the root of the disease. In the few cases in which the disease has resulted in death, and in which emboli have been found in the cerebral arteries, they probably existed as complications, and not as causes of the disease. In a few fatal cases in which post-mortem examinations were made, in some there was softening of the cerebrum, in some there were minute aneurisms, and in some no morbid conditions whatever could be found.

The etiology of the affection confirms the theory that no serious organic change is possible. A child, in perfect health, is playing out of doors when a thunder-storm comes on; the child takes refuge under a tree; a bush or tree close by is struck by lightning—the child comes home with violent chorea developed. It is hardly possible that an organic lesion could be caused by a sudden fright, and would rather regard the choreas of childhood as *functional neuroses, often associated with a rheumatic diathesis due to the presence of the rheumatic poisons in the blood, together with a lowered state of the nervous system brought on by anæmia, impairing the nutrition of the nerve-centres*. In women, chorea is frequently con-

nected with derangement of the sexual organs, and is closely associated with hysteria. Chorea in adults is a serious affection.

As regards the treatment of true chorea, we must remember that the disease is generally associated with a lowered tone of the system and with anæmia. The three chief indications are good food, proper hygiene, and tonic medication. The food should consist largely of farinaceous articles. Meat is not always the most nutritive of foods. In too large quantities it always throws a great strain on the kidneys. I am convinced that many cases of obscure kidney disease are produced by an excessive meat diet. In addition to the farinaceous foods, abundance of milk should be given. Oatmeal is also useful, but it has a tendency to open the bowels and bring on acid dyspepsia. Candies and tarts should be avoided. Put the patient in the fresh air and warm sunlight. See that he or she is also clothed in flannel from head to foot—not in merino, which is only a homœopathic tissue of wool. Silk is the best article of underclothing, in the form of heavy silk drawers and undershirts; but only the wealthy can afford it.

Among medicinal agents, iron, in the form of the dialyzed preparation, should be given in doses of twenty-five drops at meal-times. If the chorea is attended with loss of appetite, some bitter tonic may be given before meals. The tonic is the basic treatment. The bowels should be kept open without purgation. Of specifics, arsenic, given in the form of Fowler's solution, is one of the most reliable. This drug must never be given at the same time with the dialyzed iron. Fowler's solution should be administered about half an hour after meals, and in daily increasing doses until there is some slight gastric irritation, or perhaps a little puffiness about the eyes—the constitutional symptoms. Cimicifuga, too, is an excellent remedy in chorea, in the form of the fluid extract, or fresh powder. One-half a drachm of the fluid extract may be given to a young child at a dose. With the cimicifuga, arsenic may be administered and bromide of potassium given up to the point of bromism. Where these remedies fail, the sulphate or oxide of zinc may be tried. Da Costa's bromide of iron treatment has been given a fair trial in my wards, and has turned out worse than useless.

I have been for the first time trying, in connection with the present case, the drug known as skunk cabbage or dracontium. I am using a saturated tincture of the rhizoma, and am giving from eighty to ninety drops three times a day. I began with sixty drops thrice daily. If you determine ever to make use of this drug, you must not get your supply of it at the drug-stores. You will find plenty of the fresh rhizomas for sale about the markets. The best time to lay in a stock of dracontium is in the fall, and it should be at once made up into the form of a tincture. The root must not be dried before using. The effects of the skunk cabbage are probably due to some volatile principle which it contains. This woman has been taking dracontium for a short time, and is already able to notice a marked improvement of her symptoms. She has less of the jerking movements, and feels altogether vastly better.

It will not be necessary to employ gymnastic exercise, except in severe cases. Some have highly recommended the local application of ice, or of the ether spray, to the whole length of the spine. I have tried these latter modes of treatment, but without any very promising results. They may, however, cure by their action on the mind.

In a few cases, where the symptoms are intensely

severe, you want something that will for a short time absolutely put a stop to the movements. The most powerful remedy is chloral given in doses sufficiently large to force sleep. From twenty-five to forty grains of chloral, with one-quarter of a grain of morphine, may be with propriety given. Bromide of potassium is also very useful as a depresso-motor. By subduing in this way the movements, time may be gained for the employment of the arsenic.

## Original Communications.

### DESQUAMATIVE PROCESSES IN THE EAR.

By ALBERT H. BUCK, M.D.,

NEW YORK,

INSTRUCTOR OF OTOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; ONE OF THE AURAL SURGEONS TO THE NEW YORK EYE AND EAR INFIRMARY.

AMONG the cases of disease of the external auditory canal and middle ear, a few are seen in which the desquamation of epithelium, either from the mucous membrane or from the skin, forms a characteristic and sometimes a very important feature. The older authors speak of it casually under the head of impaction of cerumen in the external auditory canal, and under that of "cholesteatoma" of the tympanum and mastoid antrum. Wendt\* and Wreden† however, have quite recently called special attention to this morbid process in the middle ear and external auditory canal, and have correctly interpreted its significance. Kipp,‡ of Newark, and Blake,§ of Boston, have also reported cases in which the desquamative process was an important feature.

In an ordinary typical case of inflammation of the external auditory canal, a certain amount of desquamation almost always occurs, but as a rule it is slight in amount and not likely to attract any notice. In a few cases, however, the meatus will be found stuffed full of whitish epithelium in the form of flakes or laminae, thoroughly saturated with the inflammatory exudations of the parts. Such was the case in the following instances:

CASE I.—Male, *ætat.* 15. July 9, 1873. Healthy. Tinnitus and throbbing pain in R. ear since July 4th, immediately after bathing in the river. Examination reveals tenderness on pressure in front of right tragus; meatus filled with a loose mass of whitish epithelium; membrana tympani and cutaneous walls of canal red, swelled, and plastered over with a very whitish, thick layer of epithelium. No perforation found. H. D. W. = R.  $\frac{C}{12}$ . Four leeches to be applied in front of tragus.

July 12.—Pain slowly subsiding. Ordered instillation thrice daily of a solution of acetate of lead (gr. ij. —  $\bar{z}$  i. aq.).

July 14.—Entire absence of pain.

July 19.—The parts are still a little red and somewhat swelled. Patient did not subsequently return.

CASE II.—Male, *ætat.* 21. Sept. 17, 1873. Dull sensation and slight deafness in left ear for past two weeks. No pain; no itching; no discharge. H. D.

\* Arch. der Heilkunde, Bd. XIV., 1874.

† Arch. of Oph. and Otol., 1874.

‡ Archives of Ophthalmology and Otology, vol. iv. Edited by Drs. Knapp and Moos.

§ Archives of Surgery, New York. Edited by Dr. Bermingham.

W. = L.  $\frac{1}{2}$ . Walls of external auditory canal and membrana tympani red, swelled, and showing very slight evidences of desquamation. Ordered a two-grain solution of acetate of lead.

Sept. 20.—Swelling has materially diminished. H. D. W. = L.  $\frac{1}{2}$ .

Sept. 22.—Canal filled with white masses of epithelium. These, when placed in water, show a tendency to break up into rather thick sheets or laminae. Ordered lead solution to be discontinued, and a two-grain solution of bicarbonate of soda to be used in its stead, with subsequent syringing.

Sept. 27.—No material improvement. Patient did not subsequently return.

In these cases, for some unaccountable reason, the inflammatory process seems to have displayed its chief activity in the production and shedding of epithelium in continuous laminae of considerable extent. In that form of subacute inflammation of the external auditory canal, to which we usually give the name of eczema, there is also a certain amount of desquamation, but the epithelium is found in the form of much smaller masses or flakes. They are apt, too, to be somewhat discolored by the secretions. In the few cases in which a sufficient amount of epithelium is exfoliated to fill the canal, it will be found that the epithelial flakes are packed loosely in the meatus and can be removed without resorting to a regular mining process. The tendency to a comparatively rapid reformation of the epithelial masses is another feature which distinguishes the eczematous from the simple form of diffuse inflammation of the outer canal. The following case is an instance of what may fairly be called an eczema of the entire external auditory canal (cases of eczema of the orifice alone being very common):

CASE III.—Male, aetat. 25. December 13, 1875. Healthy, but suffers frequently from eczema. Increasing deafness during past year. H. D. W. = R.  $\frac{1}{2}$ ; L.  $\frac{1}{2}$ . On inspection both external auditory canals are found to be filled with a dirty-white or yellowish substance, consisting almost entirely of epithelium. Removed with curette and forceps. Walls of meatus red and more or less swelled throughout its entire length. No evidence of eczema on the auricle or at the outer orifice. H. D. W. after removal of epithelium = R.  $\frac{1}{2}$ ; L.  $\frac{1}{2}$ .

April 30, 1877.—More or less deafness during past two or three months, while in Florida. Precisely same condition as before; same treatment; same result.

Those cases of abundant desquamation, which occur in the course of a more or less acute inflammation of the external auditory canal, might easily lead a superficial observer to look upon the whitish membranous masses as diphtheritic in their nature; and I have no doubt that such an error has more than once been committed. The microscope, however, will always clear up any doubts on a point like this, by showing, in the non-diphtheritic cases, that the membranes are composed of large, flat, well-defined, polygonal, non-nucleated epithelial cells, with here and there a crystal of cholesteroline. The body-temperature, too, in these cases, remains normal. The question regarding the presence or absence of the fungous growth (*Aspergillus*) can of course only be settled by the use of the microscope.

In the external auditory canal the desquamative process is encountered in still another form. As the cases which we have just described (the last excepted) may fairly be classed as *acute*, so those which we are now about to describe may very properly be termed *chronic*. In these cases the patient does not consult

a physician until the morbid process has been in existence for several months, or even years. The absence of pain, and the gradual manner in which the impairment of the hearing takes place give the patient no warning of the existence of any trouble in his ear. It is only when the canal is actually full that he becomes conscious that something is wrong in his ear. An examination made under these circumstances simply reveals what seems to be impacted cerumen. It is only after a certain portion of the mass has been removed that the true nature of the obstruction can be recognized. In most cases a central core of cerumen will be found, but in others the entire mass—with the exception, perhaps, of a small portion near the outer orifice—is composed of epithelial sheets arranged (in the peripheral portions, at all events) in the form of concentric lamellae. The outermost layer is pretty closely adherent to the cutaneous wall of the meatus; very little force, however, is required to separate the exfoliated from the still living, though somewhat inflamed skin. In the vicinity of Shrapnell's membrane, and in the *cul-de-sac* formed by the membrana tympani, on one side, and the anterior and lower wall of the meatus, on the other, this adhesion seems as a rule to be strongest. In most cases the membrana tympani does not seem to participate in the desquamative process; in a few, however, it will be found actively participating in the desquamation.

As instances of this chronic desquamative process in the external auditory canal, the following cases are given in brief outlines:

CASE IV.—Male, aetat. 6. November 24, 1874. Scarlet fever three years ago followed by marked deafness, lasting, as the mother says, three or four months. Since then, hearing has been fairly good. No discharge. Both canals stuffed with laminated epithelium and a little cerumen. Foul odor from both ears. After the removal of the epithelial masses, the left membrana tympani was found to be comparatively healthy; the right, fleshy in appearance and much thickened.

CASE V.—Male, aetat. 50. Sailor, February 23, 1876. Constant dizziness and almost unbearable tinnitus in both ears "for some time past." Well-marked deafness. A plug of cerumen found in each canal. After the removal of these masses (composed simply of cerumen), it was ascertained that a tough leathery mass of laminated epithelium, grayish in color, covered each membrana tympani to a depth of not less than one millimetre, and completely filled the recess at the inner end of the meatus. The removal of these epithelial deposits was accomplished by means of the probe and forceps (an alkaline solution being used as occasion required), but only after five or six sittings. As the manipulations were necessarily more or less painful, I was obliged to make the sittings of correspondingly short duration. After the removal of the mass, the membrana tympani on both sides was found to be red, somewhat thickened, and adherent in its central portion to the opposite promontory. The dizziness and distressing tinnitus were in a great measure relieved by the removal of the obstruction, and the hearing also improved a little.

CASE VI.—Female, aetat. 35. April, 1877. Increasing deafness for "some time past." Of late has suffered greatly from a constant and very distressing tinnitus in both ears; to use her own words, "I believe I shall go crazy, if I cannot obtain relief from these noises in my head." On examination, both canals are found to be filled with tough laminated plugs of epithelium. Several sittings were found necessary

for the complete removal of these masses, which were pretty firmly adherent to the red and somewhat swelled canals. The drum membranes were also found red and moderately swelled. The removal of the offending masses afforded very decided relief, but yet did not entirely remove the tinnitus.

CASE VII.—Female, *ætat.* 41. Nov. 5, 1873. Pain in right ear during past three weeks. H. D. W. = R.  $\frac{6}{12}$ . Examination reveals the presence in the meatus of what seems to be a hard plug of cerumen. Ordered instillations of a solution of bicarbonate of soda (about fifteen grains to the ounce of water), for the purpose of softening the mass.

*Nov. 8.*—Pain has greatly increased. Patient is unable to move her jaws without causing pain in the region of the ear. While loosening the mass by cautiously introducing a slender probe between it and the walls of the canal, a drop of thick healthy pus made its escape by the side of the plug. After further manipulations with the probe the entire mass was brought away with the forceps, the greater part of it, in fact, in a single piece. A more careful examination of the plug showed it to be composed almost entirely of laminae of epithelium in a leathery condition. The inner half of the canal was dilated to fully twice its normal size, and the soft parts lining this dilated portion were in a granulating condition. At one point of only slight extent the probe encountered bare bone, not connected with a fistulous track. The *cul-de-sac* of the meatus was also a granulating surface in which no trace of membrana tympani or ossicles could be distinguished. No passage of air through the Eustachian could be effected.

On questioning the patient again, it was ascertained that for certainly twenty years she had been troubled with frequent earaches, and more or less deafness in the right ear. She denies ever having otorrhœa.

*Nov. 12.*—Entire relief from pain. No appreciable discharge.

Patient did not return afterwards.

It is important, from a therapeutical standpoint, to clearly distinguish these cases of desquamative origin from those in which the impacted mass consists simply or chiefly of cerumen. In the latter case, syringing with warm water will almost always suffice for the removal of the obstructing substance; in the former it will generally be found necessary to resort to the use of instruments. In some cases it will prove advantageous to employ an alkali for the purpose of softening the leathery masses, and thus facilitating their removal. Solutions of bicarbonate of soda of different strengths are generally employed. If an alkali solution is to be instilled into the meatus, this soda solution is probably as good as any other. A much more effective method, however, is that devised by Dr. Blake, of Boston. It is this: the end of a probe is to be armed with cotton-wool, which is then to be saturated with liquor potassæ and pushed into the centre of the epithelial plug. Wherever this strong alkaline solution comes in contact with the epithelial mass, a pulp is produced, which can readily be syringed out of the ear. The shell or tubular mass which remains can then be more easily removed with the probe and forceps than if its central support were still there.

Sometimes, in these cases of chronic desquamative trouble, an acute inflammation of the canal sets in, and, as a result of the consequent swelling, the outer orifice becomes reduced to very small proportions. Under these circumstances, it is usually a difficult matter to remove the epithelial mass, and yet it is in these very cases that the removal of the mass is most

urgently required. With a little patience, however, on the part of the physician, and some pluck on that of the patient, the narrowed orifice may be soon dilated by means of conical silver specula to the size necessary for proper illumination and operative purposes. After the orifice has been sufficiently dilated, the impacted mass should be removed by the process of mining, to which allusion has already been made. Delicacy of touch, steadiness of hand, and good illumination are never of greater service to the aurist than in such an emergency as this. On the other hand, it is hardly necessary for me to add that I do not wish to be understood as advocating the indiscriminate use of instruments in preference to the syringe. Unless he have acquired the necessary skill, the general practitioner should not attempt to use instruments in the external auditory canal; but those who have acquired this skill will, I believe, admit that there are very few occasions in which they find it necessary or desirable to use the syringe for the removal of a foreign substance from the external auditory canal.

When once the offending epithelial plug has been removed, the pain, swelling, and other disagreeable symptoms usually subside in a very short time.

The mucous membrane lining the middle ear, the mastoid antrum, and the mastoid cells may also take on a desquamative action. Thus, for example, it is not a rare occurrence in chronic purulent inflammation of the tympanum to find the mucous membrane of that cavity (the membrana tympani being nearly or quite destroyed) covered with a deposit of white epithelium, of variable thickness, and, as a rule, pretty firmly adherent to the subjacent mucous membrane. Indeed the adhesion is oftentimes so firm that the red and spongy mucous membrane is very apt to bleed when this epithelial coating is removed.

I have not yet seen (except post-mortem) a case such as that described by Dr. Kipp, or like some of those reported by Wendt. The following case, however, belongs very properly among those of middle ear origin, for the exfoliated epithelium undoubtedly was derived from the mucous membrane of the mastoid-cells.

CASE VIII.—Male, *æt.* 25. Frequent earaches and otorrhœa since childhood. Otorrhœa not constant. Pain in left ear during past three weeks. On examination (Oct. 1, 1875), the left meatus was found to be blocked up with a red fleshy mass, which sprang from the upper wall of the canal. The most prominent portion, which looked like ordinary granulation tissue, was removed with the snare, and then it was ascertained that the fleshy mass which blocked the entrance of the external auditory canal was really the prolapsed upper cutaneous wall in which an opening had established itself. A probe introduced into this opening could readily be passed in a distance of fully three-fifths of an inch without encountering at any point denuded bone. Considerable cheesy and very foul pus was removed from the contracted meatus, but no view could be obtained of the deeper parts, owing to the fact that the prolapse of the upper cutaneous wall of the canal extended inward as far, apparently, as to the immediate vicinity of the membrana tympani. As this prolapsed portion could not be lifted back to its natural position, it was evident that some substance (cheesy pus, as I supposed) had accumulated between it and the bony wall. For its removal I adapted a slender nozzle (diam.  $1\frac{1}{2}$  mm.) to an ordinary hard rubber ear-syringe, interposing between it and the nozzle of the syringe a short bit of rubber tubing. This slender nozzle was introduced without

any difficulty into the mouth of the sinus, and upon forcing in the warm water it was found that the greater part of it returned by the side of the nozzle, while the rest made its way through the sinus into the deeper parts of the ear, whence it escaped through the meatus proper. This procedure caused the patient not a little pain, and consequently could be repeated only a few times at a sitting. The first time (Oct. 2) almost nothing was brought away by the syringing, but on subsequent days the stream of water regularly brought away fragments of epithelial laminae of the most perfect whiteness. The bent forceps was also frequently used in dislodging the larger masses, which were too large to pass through the orifice of the sinus except with the aid of some tractile force. On Oct. 10th (the syringe having been used daily in the meantime) the last fragment was dislodged. The total amount of epithelium removed was sufficient to fill a two-drachm bottle (no force being used to pack the substance into small compass). A microscopic examination revealed the presence of a few crystals of cholesterine in addition to the lamellae of large, polygonal, perfectly transparent, sharply outlined, epithelial cells. From day to day, as the accumulation of epithelium became reduced in quantity, the calibre of the external auditory canal grew steadily larger, until, on the 11th of October, I was able to ascertain pretty accurately by inspection the condition of the middle ear and deeper portion of the meatus. There was at the same time a very perceptible improvement in the hearing. After the last mass of epithelium had been removed, the probe introduced into the sinus encountered roughened bone surface at the point where the posterior wall of the meatus becomes the outer surface of the mastoid process. Further inwards, however, the end of the probe passed over a series of small smooth hummocks, which conveyed to me the impression of being the exposed septa of the mastoid cells (the solid bone composing the posterior and upper wall of the meatus having been destroyed by caries—or possibly by pressure). At the farther end of the sinus, and encroaching slightly upon Shrapnell's membrane, was a second opening (in the cutaneous wall), which communicated with the inner end of the meatus, and was fringed like the outer one with granulation tissue. Upon the removal of the granulations with the snare, the membrana tympani could be seen. It was still entire, but amalgamated at almost every point with the tissues of the inner wall of the tympanum. In the posterior upper portion, and in one or two places below, the membrane was still free. There was no swelling or tenderness over the left mastoid process.

As the patient died soon afterwards (November 1st) from the results of long-standing disease in the right ear (an account of which would here be out of place), I am unable to add further details regarding the complicated condition observed in the left ear.

It is not easy to build up any theory that will satisfactorily explain all the aspects of this unusual case. Originally there was probably a severe inflammation of the middle ear which, not finding a free escape for its products through the membrana tympani—that membrane probably being more resistant than usual—extended to the mastoid cells. From this resulted in course of time a caries of that portion of the mastoid process which forms the posterior and upper wall of the external auditory canal. A fistulous opening then established itself in the cutaneous wall of the canal, and, as it was of small size and probably from time to time became closed for a short time, the accumulating pus from the carious region must have dis-

sected a way for itself in the direction of least resistance, that is, inwards towards Shrapnell's membrane. At this point, too, the cutaneous wall is thinnest, and here it was that a second opening established itself. As the mastoid cells were found to be exposed over quite an extent, without at the same time being carious, a condition which I shall not venture to explain, it is fair to assume that the immense mass of epithelium found in this situation must have been cast off from the mucous membrane lining these cells, cheesy and foul pus having originally supplied the necessary irritating stimulus. The conditions are such in this desquamative process that one is fairly justified in comparing it to a "vicious circle:" the exfoliated epithelium supplies the irritation necessary to the exfoliation of more epithelium.

## REPORT OF A CASE OF HYDROPHOBIA.

By OSWALD WARNER, M.D.,

OF PATERSON, N. J.

On Saturday, Oct. 17, 1877, I was summoned to see John W. Ashworth, aged six years and three months, and on arriving at the house learned the following history: He was a strong, robust child, of healthy parents, very intelligent and forward for his age, and had never been sick but a very few times rendering it necessary to call in a physician. When about two years of age he suffered from convulsions, for which I attended him, but do not now recollect to what cause they were attributed. No other sickness of any severity has ever occurred.

On the evening of September 10th, while in company with other children approaching his own home, a strange dog was observed lying at the door. Child-like, the little boy picked up a stone and threw it at the animal, when he made a spring at the child and caught him by the right cheek, inflicting three small punctured wounds, and immediately ran away and was seen no more.

The same dog was seen by other persons on that day acting strangely, and snapping at other dogs. The boy was taken into the house, and the wounds, which bled freely, were washed by the parents with salt and water, and some simple dressing, or perhaps none at all, applied, and healed kindly in a few days.

During the first week in October he had intermittent fever, for which the parents themselves prescribed. Recovery was rapid, and the child was sent to school.

No unpleasant symptoms of any kind occurred, until Friday morning, October 19th, when he complained of not feeling well, and had a slight fever. He was allowed to remain from school, and was in bed most of the day. The parents, supposing it to be a return of the intermittent fever, administered the same remedies they had previously done, but without benefit.

On Friday evening, quite suddenly, he showed great agitation and nervousness on attempting to drink, exclaiming that he could not drink, that his throat hurt him, and also that he had pain in the epigastrium on any attempt to do so. He was restless and disturbed through the night, with some fever, but took neither food nor drink; and when water was offered to him, he would turn from it with agitation and spasmodic action of the muscles of the throat and face, and exclaim in a fretful, peevish manner, "I can't drink," "I don't want it." During the night, when urinating,

the sound of his own water falling into the vessel produced much agitation. On the morning of Saturday, the 20th inst., a dose of castor-oil was administered, which operated in the afternoon quite freely, but neither food nor drink was taken. He remained all day much in the condition as described, in a somewhat aggravated form, and tried several times during the day, with much persuasion, to take a drink of water; but in every instance, with the spasmodic action of the muscles of the throat, he failed to accomplish it.

On Saturday morning, about 7½ o'clock, I saw him. I found him lying quietly in bed, looking only a little pale, perfectly calm, with skin feeling of about natural temperature, and slightly moist, tongue clean and moist; tonsils slightly red and swollen; perfectly rational, and willing to do anything but drink, and that he persisted in saying he could not do. I persuaded him to try, and with very great effort and spasmodic action of the muscles of the throat and general tremor, he succeeded in swallowing perhaps a teaspoonful of water or tea. Pulse was 120, and rather small and feeble. He complained still of pain in epigastrium, and also said his throat hurt him when he attempted to drink. Ordered a mixture containing gr. iij. of chlorate of potash, and gr. iv. or gr. v. bromide of potassium, to fl. ℥ i. of water, with directions that a teaspoonful be given every one or two hours, according to his condition, with all the milk he could be induced to swallow.

Sunday, Oct. 21st, at 10 A.M. I found him dressed and sitting up in a chair, looking in every way much as the night previous. He was willing, on persuasion, to try to drink, but every effort to do so was accompanied by severe spasmodic action of the muscles of the throat and face, convulsive action extending in some degree to extremities. He chewed and swallowed a lump of sugar or piece of bread with comparative ease, walked across the room several times, but with staggering, trembling and uncertain gait. Treatment continued, with the direction that the medicine be given regularly every hour.

In the afternoon Dr. J. R. Leal visited him with me. We found him in much the same condition, but with occasional paroxysms without any apparent exciting cause, and invariably upon mentioning or showing him water or any other liquid. He would, however, brace himself up nobly, and with a little persuasion make the attempt to drink, but invariably with the same result, viz., the spasmodic action, and without much success. The convulsive action was also produced by the slightest current of air or any sudden touch or movement. Tongue still moist and easily protruded; pulse 120 to 130, small and feeble. Pupils rapidly varied from wide dilatation to moderate contraction without the stimulus of light, to which they very feebly responded. He still swallows solids with much greater ease than liquids, which latter invariably produce the convulsions. The redness about the fauces and tonsils had disappeared. With Dr. Leal's approval, potass. bromide was continued, omitting the chlorate. At 9 P.M., I saw him again. Condition unchanged. Treatment continued.

Monday, Oct. 22d, at 10 A.M., I found him apparently much more quiet. Had had a tolerably quiet night, and slept several hours. Convulsions less severe and less frequent; and patient is able to drink, from a saucer held in his own hands, a few teaspoonfuls of any liquid; also to eat solids in small quantity. At my request, he washed his hands in a basin of water, and wiped his face with a wet towel. This, however, was done with very great effort and extreme

tremulousness. Did not see him again that day. Treatment continued.

Tuesday, Oct. 23d, at 8 A.M., I received a summons to see the child as soon as possible, stating that he was much worse. I saw him about 9 A.M., and found all the symptoms very much aggravated. He had slept very little, and was much convulsed during the night. Tongue was becoming very dry, and teeth and lips covered with sordes. Pulse was 140 to 150, and very small and feeble. Almost entirely unconscious and irrational. Speech very indistinct and rambling. Spasms very frequent and severe upon the action of the slightest exciting cause. He was, however, quite easily calmed, and for a short time recognized my voice and answered me rationally. At my request, he sat up in bed and ate a small piece of bread, and drank, from a saucer in his own hands, a few spoonfuls of beef-tea, swallowing with very great difficulty. While supporting him, I chanced to breathe lightly on his face, at which he complained very bitterly, and was thrown into violent convulsions, beginning with the muscles of deglutition and respiration, and extending more or less over the whole body. He had had no evacuation from his bowels since Saturday, when the castor-oil was given. Ordered an enema of soap and water—at least one pint to be given, and repeated if bowels were not readily moved; medicine to be continued by the mouth till bowels were evacuated; then small injections of beef-tea and brandy, with gr. viij. to gr. x. of potass. bromid., to be given every two hours. Eyes were becoming much suffused and injected. At 4 P.M. Dr. Leal again saw him with me, all symptoms growing worse. Pupils largely dilated, and not sensitive to light, but contracting and dilating rapidly, without any apparent cause, always, however, contracting during the convulsion. Injection had been three times repeated, giving in all about one quart, but without effect. He passed urine freely while injection was being administered, and had done so all through his sickness. Injection was repeated while we were present, a full quart being given; but no evacuation followed, and fluid was retained. Spasms almost continuous, and is entirely unable to swallow anything. Pulse 168; teeth and lips covered with sordes; tongue rather dry and dark; no flow of saliva, and very little accumulation of mucus in the throat. Ordered injections of beef-tea, brandy, and potass. bromid., to be given every two hours, and also administered morph. sulph., gr. ʒi, hypodermically, which in five or ten minutes caused contraction of pupils, and in a very short time lessened the frequency and severity of the convulsions. At 7½ P.M. he was seen by Drs. Rogers, Leal, Marsh, Balleray, and myself, and all concurred that it was a well-marked and well-defined case of hydrophobia. Symptoms were all worse. Unconsciousness almost complete. Still under the influence of morphia, as evinced by contracted pupils. Pulse so feeble that, with the recurrence of convulsions, it was scarcely to be counted, but approximated 170. Respiration 24 to 30, and irregular. Cannot swallow at all, and every effort to do so almost produces suffocation. Injections, beef-tea, brandy, and potass. bromid. continued.

Wednesday, Oct. 24th, at 1 A.M., Dr. T. J. Kane saw him with me. Every symptom aggravated. Convulsions more frequent and severe, and also general. Pupils again dilated and variable. Repeated morphia hypodermically as before, with similar effect. Injections per rectum to be continued. At 10 A.M. I found him very much more quiet; but his mother

stated that he had had a very bad, restless night throughout. He was sufficiently conscious and rational to recognize me and try to answer questions. Pulse 168, with more apparent force and volume. Influence of morphia had passed off, and pupils were again widely dilated. Repeated hypodermic injection of morphia, giving gr.  $\frac{1}{2}$ , after which he became very quiet, and convulsions almost entirely ceased. From this time he gradually sank, and died peacefully, without a struggle, at 1 $\frac{1}{2}$  P.M.

It is worthy of note in this case that many of those symptoms popularly attributed to this disease, such as barking like a dog, snarling, snapping and biting at everybody and everything, and furious delirium, were entirely wanting. This unquestionably was largely and perhaps entirely due to the calmness of the parents, who resignedly accepted the inevitable, and kept themselves free from all excitement, and in a frame of mind to administer intelligently to all the wants of the little sufferer. His age also was such that he was unable to realize the gravity of the disease, with all its attendant horrors.

## Progress of Medical Science.

**BROADHEAD ON CEREBRAL LOCALIZATION.**—The following conclusions were given in a paper read before the International Medical Congress at Geneva: 1. Paralysis is a rupture of fibres or cellules presiding over the mechanism of the nervo-motor apparatus. 2. Anæsthesia is a rupture of sensitive mechanism. 3. Tremor is the result of some impediment to the conducting power of the white fibres. 4. Convulsions, (including chorea) result from irritation of gray substance. 5. Premature and transient contracture is connected with pressure on a ganglion. According to this theory, the nervous system is a vast mechanism composed of cellules and fibres. In dismissing the question, Dr. Schiff said he did not believe in motor points in the brain, and that the *role* assigned to the corpora striata and optic thalami is not proved by clinical observation.—*Med. Press and Circ.*, Oct. 10, 1877.

**THE TREATMENT OF OZÆNA.**—Dr. Rouge, in a paper read at the third meeting of the Congress, arrived at the following conclusions:

1. Ozæna is the result of suppuration in the nasal fossæ or their annexes, viz., the frontal, maxillary, and sphenoidal sinuses, and the ethmoidal cells.

2. The suppuration appears to originate in all cases in disease of the nasal fossæ or their annexes.

3. The degree of factor of the air issuing from the nasal fossæ depends on the extent of the ossæous lesions which have given rise to the ozæna.

4. The latter is also increased by the stagnation of pus in the sinuses.

5. Should the surgeon fail to trace the disease to some affection of the nasal cavity, he must seek for it in the sinuses and the ethmoidal cells.

6. The local treatment of ozæna comprises:

(a.) Frequent washing out of the nasal cavity by means of injections, which vary with the spinal indications of each case. (b.) The insufflation of disinfecting, caustic, or astringent powders. (c.) Cauterization of various kinds; the use of the galvano-cautery. (d.) In severe cases all sequestra must be removed,

and the sinuses completely drained. The nose is detached by the sub-labial method; this enables us to explore the nasal fossæ directly, to remove all necrosed portions of bone, and to open the sinuses. The formation of a cicatrix is thus avoided.

7. It is unnecessary to speak of any general mode of treatment, as this must be regulated according to the patient's constitution.

M. VERNEUIL said he had not applied the method of Dr. Rouge, but he would do so. He remembers that M. Trelat had some good results from it.

DR. OLLIER adopted this method in certain cases.

DR. ROUGE believed that ozæna is generally due to alteration of the sinuses, but more frequently to caries of the ethmoidal cells. Posterior rhinoscopy is not so useful, because the mucous membrane is so swollen that we cannot conveniently discover the diseased parts.—*Med. Press and Circ.*, Oct. 10, 1877.

**CHLORIDE OF CALCIUM.**—Dr. Robert Bell recommends the chloride of calcium as a therapeutic agent which deserves a more complete recognition than it has of late received from the profession. Having used it extensively for the last four years, and having closely observed its effects, he feels justified in asserting that, in most forms of tubercular disease, and in the wasting diseases of childhood, whether tubercular or not, it is a remedy of inestimable value. It seems to possess a direct influence over assimilation, and Dr. Bell uses it in all cases in which the symptoms show a strict observance of dietetic rules. The remedy was put to a crucial test in the Cambridge Street Orphanage for Girls; here, the majority of the girls, when admitted, showed unmistakable signs of tubercular disease; every case in which the drug was used improved many of them rapidly, and the majority appear to have shaken off the disease entirely. In tubercular disease of the bones and joints of children, and in affections of the cervical glands, due to the same cause, Dr. Bell has never met with its equal. Several cases of pulmonary phthisis treated with this salt gave most gratifying results, especially in the early stages. The only case of tubercular peritonitis that came under Dr. Bell's notice, during the period of observation, yielded completely to the remedy. In conclusion, he says, that, as the medicine requires to be perseveringly used, the physician should not be discouraged by an apparent failure, but should give it a lengthened trial. Muriate of calcium can do no harm to the economy, and in many cases will be of incalculable service. In a communication to the Doctor, Sinclair Coghill speaks in equally high terms of the efficacy of this drug. Well known and highly esteemed up to fifty years ago, it has been completely crowded out by iodine and cod-liver oil. The most convenient form of administration is a solution of the crystals of the salt, in  $\frac{3}{4}$  viij.–xij. of distilled water, of which the dose for an adult is  $\mathcal{U}$ . xx.–l. in milk or syrup.—*Lancet*, Aug. 25, 1877, and *Practitioner*, Aug., 1877.

**ERRORS OF THE SPHYGMOGRAPH.**—In the *New York Medical Journal* for November, Dr. Edgar Holden draws attention to some of the most frequent causes of error occurring in the use of the sphygmograph. He classifies errors into those of comparison, of observation, and of interpretation. Errors of the first class may arise from comparison of records taken by different instruments, or at different degrees of pressure, or upon different arteries, or at different rates of speed, and may be so great as to vitiate the importance of the observation. Errors of the second class include those arising from carelessness, or from want of proper appreciation of purely physiological

causes, as full meals, fatigue, etc. Errors of interpretation occur when peculiarities of a tracing are not attributed to their proper causes. "A singular and not easily explained error may arise where aortic regurgitation exists. When the heart, under the stimulus of the regurgitant flow, has come into a state of hyperexcitation, the tracing, before exhibiting unmistakable evidence of regurgitation, gives the low, flat-topped record of high arterial tension, the sudden drop of arterial collapse having disappeared. In such a case, proper adaptation of pressure can alone give a correct record." He concludes with the following summary:

1. In all tracings published, the reader should be informed of the prominent features of the case, if one of disease, and if one of supposed health, of the condition as regards meals, exercise, habits, and temperament.

2. The degree of pressure should be stated.

3. The instrument used, and the rate of speed, with the number of pulsations by actual count, should be given, as well also as the name of the artery tried.

4. The greatest care should be exercised, not only to obtain a perfect record, but the particular record which, after several efforts at different pressures, is found to be the true exponent of the condition.

**REPEATED EXCISION OF THE INFERIOR DENTAL AND GUSTATORY NERVES FOR THE CURE OF DENTAL NEURALGIA.**—In a paper read before the Detroit Medical and Library Association, Dr. McGraw relates the following case: The patient suffered from neuralgia of the lower jaw, left side. In February, 1873, Prof. Gross, of Philadelphia, trephined the horizontal portion of the bone and destroyed the nerve. This gave relief for over a year, when the pain returned in the jaw, and made its appearance, for the first time, in the tongue. In June, 1875, Dr. McGraw trephined the ramus of the jaw, and excised about half an inch of the inferior dental and gustatory nerves. After this operation pain remained absent for fourteen months, when it again returned. Acting on the suggestion of Richet, Dr. McGraw then divided the auriculo-temporal nerve, without any effect on the neuralgia. Shortly afterwards he performed the operation recommended by Prof. Gross, and removed the whole of the alveolar process of the left side of lower jaw, with a similar result. Believing that the nerves had become regenerated, he determined to divide them nearer their origins, and to tear them loose from their connections, as is frequently done with such success in neuralgias of traumatic origin. Accordingly, on September 28, 1876, the nerves were laid bare and carefully examined, but without finding any break in their continuity at the seat of the former operation. Powerful traction was then applied in the endeavor to loosen them from their attachments, but in vain, and it was found necessary to cut them, about three-quarters of an inch being removed from each. The wound healed rapidly by granulation, and up to this time there has been no return of the neuralgia.—*Detroit Medical Journal*, November, 1877.

**USE OF CARBONIC ACID GAS AT VICHY.**—Carbonic acid is employed at Vichy in the form of general and local baths, in douches and injections, and by the stomach. For the general baths ordinary bath-tubs are used, which are simply covered with an impermeable cloth, destined to protect the head. The sittings last from twenty minutes to an hour. In the local baths the affected limbs are simply enclosed in cloth

or caoutchouc bags, into which the gas is then introduced. These baths have been used with more or less success, to relieve the pains of gout and rheumatism, of sciatic and other neuralgias, etc. In these cases the gas exerts an analgesic and a diaphoretic action. For douches and injections, the gas is conducted to the diseased parts by means of flexible caoutchouc tubes. These douches and injections have given excellent results in cases of pruritus and spasm, in the different vaginal and uterine neuroses, which are so often the cause of sterility, and in ulceration of the cervix uteri. Most of the cases of simple ulceration of the cervix heal rapidly under the treatment. The injections, however, must be used with some caution, for when the mucous membrane is inflamed and excoriated, a dangerous quantity of the gas may be absorbed by the denuded surfaces. The administration of the gas by the stomach does not seem to be of much use.

The analgesic and cicatrizing properties of carbonic acid have been demonstrated by the experiments of Ingen-Housz and others. It relieves the pain of a blister almost immediately, and hastens the reformation of the cuticle. When the gas is injected into the bladder or vagina, a slight sensation of tickling and heat, which radiates towards the abdominal region, is felt at first, but it is soon followed by relief of the hyperæsthesias, and sometimes by complete cessation of the pains. Follin has employed injections of carbonic acid gas in the treatment of cancerous ulcers of the cervix uteri. In two cases they relieved the pains completely and rapidly; in one the relief lasted twenty-four hours, in the other eight days. Of course, the injections had no other influence on the general or local condition. In cases of rheumatic paralysis the carbonic acid baths seem to prove very useful in restoring the power of motion.—*Le Mouvement Médical*, Oct. 20, 1877.

**EXPERIMENTS ON THE DEVELOPMENT OF THE TÆNIA SOLIUM IN MAN.**—There has been considerable discussion over the question whether or not the cysticercus of man is identical with the cysticercus of the pig. If it be true that the cysticercus of man is the second phase of development of the tænia solium, the parasite will also be found in its perfect strobiliform state in the intestines of man, and in all probability there alone. To settle this point, a M. Redon, of Lyons, swallowed in warm milk four cysts taken from the body of a dead man. As, however, it was possible that these cysticerci had been derived from a tænia carried by some animal with which the man had been in frequent relation, M. Redon also administered a number of the cysts to some sucking pigs and dogs. The pigs all succumbed to enteritis, and at the autopsies the most careful examination failed to reveal any traces of the parasite. The dogs also did not contain any traces of the tape-worms. With M. Redon himself, however, the case was different. After an interval of three months and two days he found links of the worm in his passages. These were examined and found to belong to the tænia solium. Shortly afterwards an entire strobilus was passed, which will be placed in the medical museum at Lyons. These experiments settle the question of the nature and development of the cysticercus of man; they present, moreover, a striking exception to that apparently so absolute rule of the development of the parasites: that the same parasite cannot attain its complete development in the same individual or in two individuals of the same species.—*Gazette Méd. de Paris*, Oct. 20, 1877.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, December 15, 1877.

## A MOVEMENT FOR HIGHER CULTURE IN THE MEDICAL PROFESSION.

THE first annual address of the President of the American Academy of Medicine, delivered by Prof. Traill Green, A.M., M.D., etc., of Easton, Penn., at the meeting of the Academy, in this city, in September last, has been printed in a neat pamphlet, which embraces the constitution and by-laws of an organization that, if rightly managed, is destined to exercise a commanding influence upon the culture and *morale* of the medical profession in this country. It is pardonable, therefore, to express in advance the hope that mere collateral issues will not be permitted to divert the attention of the Society from the purpose for which it was formed, namely, "To encourage young men to pursue regular courses of study in classical and scientific institutions before entering upon the study of medicine, and to extend the bounds of medical science, and elevate the profession." As the title and style, "American Academy of Medicine," will be new to many of our readers, it should be premised that the September meeting was its first regular annual session, and that the Society aims to bring those who are alumni of *both classical (or scientific) and medical schools* into closer relations with each other. With this end in view, the constitution prescribes that the fellows of the Academy shall be alumni of respectable institutions of learning, having taken the degrees of A.B. and A.M., in accordance with the usages of such institutions, in addition or preliminary to the degree of Doctor of Medicine, obtained after a regular course of three years in a medical school. An exception is made, however, in favor of candidates from medical colleges that require of their graduates evidence of preliminary academic study equivalent to a thorough collegiate course, and in favor of those who have pursued systematic courses of study in institutions not entitled to confer the degree of A.B., but whose culture in the classics and the

sciences would be sufficient to command the degree after a thorough examination. These are not exactly the terms, although they express the substance of constitutional provisions that aim to exclude from the fellowships of the organization the mass of ignorance and half-culture which overloads the medical profession in this country, lessens its influence, and in a measure defeats the important ends of sanitary and other reform advocated by its most enlightened members. The fact that a considerable percentage of the men engaged in practising medicine are not entitled to be styled either scientific or liberally educated men, is too familiar to the general observer to call for comment. It is, indeed, one of those unpleasant facts that the ablest and most cultivated men in the profession have constantly to deplore, although the best way to correct it is a question that admits of more discussion than is practicable in a medical journal. If all our medical colleges, as is now the case in England, France, and Germany, would concur in making the degree of A.B., or a classical training equivalent to that, one of the conditions of admission to their classes, there would, of course, be no need to initiate such a movement as is represented by the American Academy of Medicine, and the elimination of uneducated practitioners would become a question of one generation only. Direct prescription by legislation, or exclusion from medical associations of the actual graduates of medical schools who have not followed preliminary courses of study, would, again, accomplish the result. But unfortunately, as respects medicine, public sentiment, which controls medical colleges as well as legislation, has not yet been taught to appreciate the importance of a liberal education in training the mental faculties to those habits of exact and logical thinking which are as essential to correct diagnosis, and to the consistent application of remedies, as they are to the resolution of a quadratic equation or to the composition of a sermon. On the contrary, the idea that a little special training in anatomy, physiology, and the materia medica, is all that is necessary to make a successful physician or surgeon, is entertained in circles where the advantages of liberal culture to a clergyman or lawyer are fully conceded. Yet, as Prof. Green argues, physicians, more than clergymen and lawyers, require a cultivation and training of the mental faculties competent to meet and deal with sudden emergencies. The clergyman has leisure to prepare his sermons; the lawyer to examine his authorities; while the medical practitioner has often to determine upon issues of life and death, without premeditation, and actually upon the spur of the moment. The mental alacrity and the command of intellectual resources essential to acquit one's self creditably in such emergencies are not things that come by instinct or by a scanty three years' discipline in a medical school. A barber takes that period of apprenticeship to learn to wield a razor, and scarcely

regards himself as an accomplished tonsor until years of after-practice have trained his hand to a delicacy that was inconceivable to him at the outset of his career.

It is scarcely necessary to expose the absurdity of popular sentiment on this point to a constituency of medical men, most of whom have already arrived at the conclusion expressed by Sir James Martin, at the last meeting of the Irish Medical Association, that unless serious and determined measures are taken to insist upon a higher standard of preliminary education, the standing of the profession, social as well as scientific, must necessarily deteriorate year by year. Those who have the welfare of the profession at heart will, however, on looking over Prof. Green's address, be thankful for the evidences he has furnished that the movement initiated by the American Academy of Medicine is not only a necessary one, but also one as to the necessity of which the ablest physicians in Europe as well as here, are in substantial agreement, although the European standard is far in advance of ours. The importance of the movement is, indeed, evinced by the fact that a recent General Medical Council of Britain, composed of the most eminent British physicians, spent thirteen days in discussing the subject of preliminary and professional examinations. In the course of this debate, Dr. Farr, the medical statist, instanced the fact that "it has become a matter of public concern that it is difficult to supply the vacancies in the army medical staff with competent practitioners." This state of medical incompetence every member of the Council concurred in tracing to the low standard of preliminary education common to students in British medical colleges, although a certain academic training is demanded by all of them.

Dr. Green has brought out *in alto relievo* another point, upon which possibly there might have been some difference of opinion had he not thoroughly collated the evidences that sustain his position. It is, that the medical profession is indebted to physicians of liberal culture for every marked advance that has distinguished its progress since Linaere (1518) was instrumental in establishing the Royal College of Physicians in London. For the data that sustain this position readers must be referred to the address itself, which, as respects this topic, is one of the most creditable examples of professional erudition that have recently been issued in this country, and will subserve the cause of medical learning in a signal manner, if it is successful in convincing the young men of the profession that discoveries are not usually results of happy blundering, or great reputations of a series of fortunate accidents. On the contrary, there is a constant relation between liberal culture (that renders the physician a gentleman and a scholar) and distinguished professional success. Unfortunately, exact statistical information as to the percentage of students in our medical colleges who have had no preliminary

training, as compared with the whole number, is not accessible, owing to the fact that literary attainments are not made matters of register. The medical school of Harvard University has probably more than its fair average of students holding academical degrees, and of a recent graduating class there, consisting of sixty-one members, the number was only twenty-seven. Perhaps, considering the exceptionally literary atmosphere of Harvard, no better illustration of the lack of liberal culture in the medical profession in this country could be furnished, nor a more humiliating comment upon its literary standing.

It has not been our purpose in the preceding remarks to follow Prof. Green's argument, or even to justify the movement in which it originated. That justifies itself, and need not assume the apologetic tone. It would be a matter of lasting regret, however, to the more enlightened members of the profession, if such a movement were to languish for want of proper publicity and of sufficient discussion in our medical journals. In this view of the case, as pamphlets are seldom read and generally find their way into obscure pigeon-holes in a doctor's office, particular attention has been called to a few leading propositions by way of enlisting the enthusiasm of those in sympathy with liberal culture, and of piquing the curiosity of the many who are neutral or opposed to it on personal grounds. The latter, of course, will have something to say about medical snobs. But a careful perusal of the pamphlet will convince the average practitioner that the standing of the profession is menaced by the existing method of conferring diplomas upon ploughboys.

#### CONTAGIOUS DISEASES AND PRIVILEGED TESTIMONY.

A PHYSICIAN of Brooklyn has recently refused to report cases of contagious diseases to the Board of Health of that city, on the ground that such information is privileged. As he wishes to test the legal authority of health boards in regard to the point at issue, he will be prosecuted accordingly. The stand taken is a novel one, and will doubtless bring up many interesting points bearing upon privileged professional testimony. The profession would doubtless like to see many of them settled, but there is little hope that much can be accomplished in that direction by any action based upon such a plea as we have named. The assumption that such testimony is under the circumstances in any legal or moral sense privileged, is absurd upon the face of it. The object of preventing the disclosure of any information acquired in a professional capacity is quite plain. All other things being equal, the patient making any confession to a medical man, which confession is necessary to enable him to prescribe, must on principle be protected. The very term confession implies the recital of facts of a confidential character, the disclosure of

which may be damaging to the confessing party; but "the confession, in order to be protected against disclosure, must relate exclusively to such matters as are indispensable to the professional treatment of the patient. Communications made outside of this sphere acquire no immunity from having been entrusted to physicians, for at common law such are not deemed privileged, and wherever so recognized they are the creatures of statutory enactment" (*Ordronaux's Med. Jurisprudence*, § 121). Necessarily, then, all such communications must be of a lawful character; that is, not against morality, public policy, or public safety. Whenever any of the latter conditions are present, the principle of common law compels the sacrifice of the rights of the individual for the protection and maintenance of those of the majority. Viewed in such a light, the man with a contagious disease has no right, directly of himself or indirectly through his physician, to interfere with any measure calculated for the public safety. The moment a man becomes the victim of a contagious disease—on the principle of sacrificing the lesser to the greater—always a cardinal principle in law—he for the time being loses his personal liberty, becomes a public nuisance, and must for a certain time be taken care of.

## Reviews and Notices of Books.

TRANSACTIONS OF THE NEW YORK PATHOLOGICAL SOCIETY. Vol. II. Based on the Proceedings of the Year 1875, and largely supplemented from the Records of 1844 to 1877. Edited by JOHN C. PETERS, M.D., President Medical Society County of N. Y. New York: W. Wood & Co. 1877. Svo. pp. 291.

THE second volume of the Transactions of the New York Pathological Society comes to us with a rapidity which is surprising even in this age of book-making. In many respects it is superior to the first, not only in the general arrangement of the subjects treated, but in the improvements in their manner and method of presentation which the maturer experience of the editor has enabled him to make. The volume deals largely—in fact, almost wholly—with abdominal lesions, some of which are of the rarest possible kind, while all are of the greatest practical interest to the progressive practitioner and the earnest working pathologist. Almost every disease met with in the abdominal cavity has a counterpart in this volume, while some of the more common ones are presented in comparatively large numbers. For instance, there are detailed 89 cases of perforation of the intestine, 33 of perforation of the appendix vermiformis, 5 of perityphlitis, 35 of intussusception, 21 cases of operations for intussusception, 30 cases of stricture of rectum, 23 cases of imperforate rectum, 13 cases of disease of the pancreas, 12 cases of portal phlebitis. Dr. Peters has excelled himself in the preparation of this volume, and has placed the Society and the profession at large under lasting obligations to him, not only for editing the Transactions, but for presenting what might almost be considered a text-book upon the pathology of the most important and interesting regions of the body.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, Nov. 14, 1877.*

DR. E. G. JANEWAY, PRESIDENT, IN THE CHAIR.

CASE OF CHRONIC ULCERATIONS OF LARYNX IN A PATIENT WITH CATARRHIAL PHTHISIS—LARGE GANGRENOUS CAVITY OF RIGHT LUNG—DEATH PROBABLY DUE TO OEDEMA OF ARY-EPIGLOTTIC FOLDS.

DR. BEVERLEY ROBINSON presented a larynx with the following history:

J. B., æt. 17 years, died in the penitentiary hospital on Blackwell's Island, Nov. 1, 1877. Deceased entered my service seven days previous. At that time he was suffering from almost constant cough, followed by fetid, purulent, and frothy sputa. The dyspnoea was intense, and the inspirations stridulous. The voice was very hoarse, and the patient complained of pain in his throat and a feeling of suffocation. He said he had had sanguinolent expectoration on several occasions, and had been troubled with more or less cough for several years. Patient was very weak, took but a small quantity of food, and had considerable nausea. Temperatures ranged from 100½ Fah. to 103½ Fah. P., 86-96.

*Physical examination* revealed marked dulness over anterior region of right lung. There were no signs of a cavity at this level, and, indeed, few or no râles. Vocal resonance about normal. No morbid signs were found anywhere in the left lung, beyond a few disseminated bronchial râles. Posteriorly, there was dulness on percussion over the entire right side of the chest, but no other signs of liquid effusion. There were a tolerable number of moist bronchial râles, of medium size throughout, but the usual manifestations of a cavity were not discovered.

My diagnosis was, probable catarrhal pneumonia, having undergone, in places, gangrenous change; old pleuritic adhesions covering a large portion of right lung, and possible incomplete paralysis of abductors of vocal cords. Laryngoscopic examination made two days afterwards showed intense congestion of epiglottis and ary-epiglottic folds. The right vocal cord was seen by one of the house staff to have normal movement, though intensely congested. Left vocal cord could not be recognized, owing to folding of epiglottis upon itself. At 3 A.M., Nov. 1st, interne, Dr. Paine, was sent for, only to find patient dead upon his arrival in ward. It was thought by him that patient died from rapid serous effusion into soft tissues of the ary-epiglottic folds. This belief is apparently justified by the post-mortem record of the Curator, Dr. Spencer.

The autopsy, in the main, confirmed the diagnosis made prior to death, of the nature and extent of the intra-thoracic lesions. "At the base of right upper lobe of lung and upper portion of middle, however, a large gangrenous cavity, partially filled with debris of very offensive odor, was found." The condition of the larynx was as follows: "The tissues of the epiglottis very lax and curving inward; its mucous membrane just above ventricular bands show numerous small superficial ulcerations. The vocal cords (?) of both sides show œdema, but that of left side more marked, and so much as to almost obliterate sacculus of this side" (Spencer).

*Remarks.*—The ulcerations of the larynx are evidently catarrhal in nature, and there is, at least to oc-

ular examination, no tubercular deposit. The interest of the specimen relates in great measure to the question, what is laryngeal phthisis? Is it simply the irritation and ulceration of the glands of the larynx resulting from the passage of pulmonary sputa over its surface? Are tubercles at times developed in its tissues?

SHOULD TRACHEOTOMY BE PERFORMED IN ULCERATIVE LARYNGITIS.

If the former belief be the correct one, how far is it justifiable to perform tracheotomy in the earlier stages of ulcerative laryngitis of this nature, as a means of cure? Manifestly, if it be possible to prevent frequent contact of purulent fluids with a surface upon which they have occasioned disease and are still maintaining it, the patient would have a better chance of local cure than if the morbid process be allowed to run its course without interference. Tracheotomy is our sole means of doing this, as it is the sole means also of preventing incessant action of the vocal cords during respiratory movements and injurious effects of influx of atmospheric air upon a raw membrane in inspiration.

DR. FLINT had never met with a case of laryngeal obstruction causing death, which obstruction was due to phthisis.

DR. JANEWAY said that a great deal depended upon what should be considered as phthisis. The views of pathologists had very much altered in regard to this question, from what they were several years ago. For instance, Rindfleisch, in his last edition, is very different from what he was five years ago. Then he believed that there was very little of pure tuberculous disease in existence, but now he has taken an entirely opposite view. The same was true of other pathologists.

DR. ROBINSON: There is a great difference of opinion whether pneumonic disease is tuberculous or not.

DR. SATTERTHWAITE: As to the nature of gray tubercle, as distinguished from anything else, there can be no question, as the microscopical appearances are always uniform.

DR. JANEWAY: But in most cases ulceration complicates the original condition, and what was gray tubercle first becomes entirely changed. The death in the cases referred to by Dr. Robinson has been due to lung disease, but not from laryngeal trouble. The latter is so entirely dependent upon the former that all indications for treatment centre themselves accordingly. If the cough were mitigated and the lung trouble cured, the larynx would take care of itself.

DR. LOOMIS was inclined to take an opposite view. In his experience, patients with tuberculous disease did very well until laryngeal trouble showed itself. He regarded the latter condition as a very grave and ominous one. Such cases usually break down very rapidly. He believed that tracheotomy would be of great service in such cases, in fact, such an idea had occurred to him more than once.

DR. JANEWAY: If there is ulceration of the larynx, tracheotomy will not relieve the difficulty of swallowing. Again, the mere presence of the tube in the trachea, and the irritation caused thereby, is an element which must be taken into account in advising the operation.

DR. LOOMIS: The testimony of those who have had experience in the operation is to the effect that it affords relief.

DR. FLINT: As far as my experience goes, the laryngeal complication becomes grave only when associated with difficult deglutition. Aside from this I do

not look upon it as an unfavorable event with respect to the duration of the disease.

DR. LOOMIS remarked that there were two forms of laryngitis in connection with phthisis, one form which developed at the same time with the disease in the lung, and progressed *pari passu* with it, and which were rapid cases; another form, which commenced as ordinary catarrh of the trachea and bronchi, followed the tubes downwards and eventually developed into phthisis. These go on without laryngeal complication until late in the disease, but with such a complication the end is near.

On motion, Dr. Robinson's specimen was referred to the Microscopical Committee.

ARTHRITIS DEFORMANS IN CHILDREN.

DR. E. C. SEGUIN presented two living specimens of chronic rheumatic arthritis (arthritis deformans) in infancy. The family consisted of four children. Of these, three had the disease, one boy and two girls. In all, the disease developed itself from the age of 2½ to 4 years. In none of them were there any symptoms of progressive ankylosis. The disease commenced in the last phalanges, then attacked the second row of joints, and thence to those of the wrist, elbow, and feet. There was no difference in the three histories, and no difference in the appearance of the three children. The parents were free from any disease. There was no assignable cause for the trouble in the children. They were under galvanic treatment, with possibly some slight benefit. The extreme rarity of this condition in infancy constituted the interest in the cases.

DR. GIBNEY referred to a case of a boy aged seven years which he had under observation for the past three years. When first seen, every joint in the body was affected with arthritis deformans.

DR. JANEWAY alluded to a similar case in a female 19 years of age.

EXSECTION OF HIP, WITH APPARENT RECOVERY.

DR. MASON presented a colored lad, aged 19 years, upon whom he had operated in July, 1876, for morbus coxarius by exsection of the hip. The patient entered the Colored Home, July 7, 1876. He enjoyed perfect health six months ago, when climbing on a hay-loft he fell a distance of six feet, striking on his right hip. For three or four days after he suffered considerable pain and swelling in the part, and in three weeks afterwards an abscess formed under Poupart's ligament, and a great deal of pus was evacuated. From that time several spontaneous openings appeared around the joint. At no time was there any pain referred to the knee. July 29th the operation of exsection was performed. The head, neck, and two inches of the shaft of the femur were removed. All the portion of the femur was much enlarged, the head of the bone was necrosed, the acetabulum was diseased and was duly scraped away, and the patient was placed upon Buck's extension. This was all the treatment he had. On Nov. 28th he walked about with crutches, and on the following January walked without them, and since that time he has been employed as an errand-boy at the Colored Home. The shortening was one and a half inches. The lad, to all outside appearances, was perfectly well. He could walk a half a mile without fatigue, flex his thigh upon the pelvis, and bear the whole weight of the body on the limb. But there existed no less than fifteen sinuses, five of which were situated in the gluteal region, and through two of these, at least, bare bone can be reached. In a word, the disease had progressed after the operation,

and yet, generally speaking, the patient was doing so well that any attempt to remove the necrosed tissue was not warranted. The urine was perfectly healthy.

DR. GIBNEY stated that he had a case under observation upon which the operation of exsection of the hip had been performed many years ago, and in which with apparent recovery there were still evidences of disease both in the acetabulum and femur.

DR. POST stated that six years ago he was called to Jersey City to see, in consultation, a boy ten years old, who had disease of the hip-joint in an advanced stage. His thigh was bent upon the trunk at an acute angle so that the knee was almost in contact with the chin, and there was no motion at the hip. The patient was suffering great pain, was very much emaciated, had hectic fever, and altogether seemed to have a very short time to live. He was etherized, and the limb was brought, by a moderate degree of force, down in a very nearly straight position, which was maintained by the weight and pulley. Actual cautery was applied freely behind the trochanter, and the improvement of the patient was very rapid. He was enabled to rest comfortably, his appetite improved, and he was brought to the city about six months afterwards in apparently good health. He had gained twenty pounds in flesh, and the hip being ankylosed in the straight position he was entirely free from deformity.

He spoke of this case in that connection because on the Saturday previous he had an opportunity of seeing the joint removed post mortem. There was perfect ankylosis of the thigh, but the pelvic bones after a lapse of six years were eroded and carious, and eventually caused the death of the patient.

#### ARTERITIS OF ARTERIES OF ARM AND GANGRENE OF HAND.

DR. POST then presented the brachial, ulnar, radial, and interosseal arteries removed from a man 58 years of age, who was under his care in the Presbyterian Hospital. He was brought into the institution in a very feeble condition, suffering from spontaneous gangrene involving nearly the whole of the left hand. The disease came on very gradually, and was attended with great emaciation and debility. During the short time he was in the hospital his stomach was in a very irritable condition, and during a portion of the time he vomited almost incessantly. After death it was found that all the arteries of this extremity were thickened and atheromatous, the radial artery being occluded by a clot. In addition to his other disease, the patient had cancer of the stomach, which explained the cause of the vomiting. The plugging in this case was evidently due to arterial thrombosis following arteritis.

Dr. Post presented a tubular sequestrum removed from a patient who had furnished similar specimens to the Society, and who had suffered since the August previous with multiple disease of the bones. The specimen in question was removed from the right os brachii high up, and subsequently to a similar piece of bone having been removed from the same bone lower down. The former piece was tubular in shape, and extended quite up to the head of the bone.

He next exhibited a loose cartilage removed by operation from the theca of the index finger of a young man aged twenty. The point of interest was the unusual size of the growth in that situation.

He next presented exsected joints from the index and middle fingers of the left hand. These joints were removed by operation from a girl, aged fifteen years. Both of her hands had been very badly burned,

and during the healing process the fingers in question had become badly ankylosed at an angle which denoted about twenty degrees from the right line, and gave the hand a very awkward appearance. The operation connected the deformity, and the wounds healed without difficulty.

#### ASPIRATION FOR SUBACUTE PLEURISY—WAS THE PERICARDIUM PUNCTURED?—RELATIVE VALUE OF THE HYPODERMIC NEEDLE AND TROCAR.

DR. LOOMIS presented a specimen which was removed from a native of Denmark, aged forty-five years, and which was chiefly of interest in connection with the history of the case. He had led an intemperate life, but said that he had never been sufficiently ill to keep his bed until one week before his admission. He was then seized one afternoon with a severe chill, which was followed by an intense fever, lasting him through the night. He was so far relieved in the morning that he was able to go to his business—that of paper-hanging. During the day he felt ill and weak, and for the first time noticed a pain in his left side. This pain gradually increased; he lost his appetite, and was part of the day in bed, and part of the day sitting up until he came to the hospital, when he began to suffer from difficult breathing. He had a very anxious countenance; temperature, 103° F.; pulse, 120, and feeble; and was unable to lie on the right side. Dr. Wheelock, house-physician, examined his chest, and found evidences of fluid in the left pleural cavity. He also stated that he noticed an expectoration which he thought was pneumonic, but saw only one or two specimens. The second day after his admission, Dr. L. made his first examination, and found the patient with blueness of the lips; breathing rapidly (60 per minute); short, catching respiration; temperature, 102°; pulse, ranging from 120-130, and feeble. On attempting to sit up the lips became bluer. There was loss of motion of the left chest, and abnormal increase of motion of the right chest. There was an entire absence of fremitus over the whole of the left side, above and below. On percussion, there was flatness over the whole of the left chest, extending over to the right of the median line in front. The apex of the heart was found beating to the right of the median line, and feeble; best felt when he was sitting up; was not distinct when lying down. On auscultation, there was entire absence of respiratory murmur over the left chest. The heart-sounds were not distinctly heard in the normal position at the apex. There was a loud and tubular quality of bronchial breathing heard over the whole of the left chest except in front. There were no râles on either side of the chest, and no friction-sound over the precordia.

The diagnosis was made of subacute pleurisy, or, rather, acute pleurisy with a large amount of effusion. The question of pericarditis was raised, but Dr. L. was unable to answer it. Within a day or so after this, as the dyspnea rapidly increased, and had reason to fear congestion and œdema of the other lung, aspiration was advised. The house-physician introduced a needle in the ordinary position in the infra-scapular space. The needle was passed in two inches, perhaps a little more, and two ounces of blood, which subsequently coagulated, was drawn. The house-physician then ceased any further attempts until Dr. L. should see the patient again. Then aspiration was repeated, and fourteen ounces of fluid were drawn off. The point of aspiration was at the junction of the axilla and infra-scapular spaces. When the fluid ceased to flow, the end of the needle was moved to enable more fluid to flow. The patient was temporarily relieved by the

operation. Soon after, however, the dyspnoea increased, and he finally died on the 27th, apparently from invasion of the opposite lung.

At the autopsy, the pericardium was distended with a serous fluid stained with blood. The visceral and parietal portions of the pericardium presented very easily-recognized appearances of acute pericarditis. The left pleural cavity was filled with a clear fluid. There were one or two points of interest in this case. The first one had reference to the difficulty in diagnosis. This was always the case when there was pericarditis with effusion and pleurisy, with effusion on the left side. The heart-sounds were heard quite distinctly to right, but not to the left or upwards as far as might have been expected with a distended pericardium. The second point of interest referred to the operation of aspiration, and the source of the blood following the operation. Two ounces of coagulable blood do not often follow the introduction of a needle into the lung. The question might arise, Did the needle pass into the pericardium? Without committing himself positively on this point, Dr. Loomis wished to record his objection against the use of needles in aspirating the chest, and expressed his preference for the small trocar and canula.

DR. BRIDGON asked if the supposed danger in the use of the needle did not in some measure refer to its size.

DR. FLINT said that he had objected to the needle for several years, for the reason that its sharp point was apt to injure the visceral pleura, to scratch the lung during respiration, or during any miscalculated movement either on the part of the operator or patient. With the trocar canula, however, this objection did not obtain.

DR. LOOMIS stated that within the past two or three weeks he had aspirated two or three cases of subacute pleurisy without obtaining any fluid.

DR. JANEWAY referred to similar instances, the failure in obtaining fluid being due evidently to an extra thickness of a loose membrane which was pushed before the needle in its entrance, or by flocculi of lymph which plugged up the canal.

DR. FLINT stated that the latter condition was the one which occurred in the first case operated upon by Dr. Bowditch.

#### GOUTY DEPOSITS.

DR. BRIDGON exhibited the metatarso-phalangeal articulation of the great toe, showing gouty deposit. The specimen was removed post-mortem from a medical gentleman who had suffered from gout for the past ten years, and also from hemorrhoids. Finally, the kidney became affected, there was an attack of intercurrent pleuro-pneumonia, then followed a waterlogged condition of the system. From this he partially recovered, when tuberculosis followed, from which he eventually sank. The joint in question presented well-marked deposits upon the articular surfaces, and was a typical specimen of its kind.

#### PIECE OF LENS CAPSULE REMOVED DURING A CATARACT EXTRACTION.

DR. H. KNAPP said that he had to show a microscopic specimen only which in itself was of no account, but might be of some interest by the manner in which it had been acquired, and the practical hints it might suggest. It was a piece of the anterior capsule of the crystalline lens, two to three lines in extent, and proved, under the microscope, to be a perfectly normal capsule lined with its epithelium. It was taken from a very old and decrepit woman. When the ex-

traction of the cataract was completed, the inner part of the section was covered with a thin film of coagulated blood. Though many surgeons were of opinion that such a small quantity of coagulated blood should be left, since it favored agglutination in acting as a kind of cement, Dr. Knapp, not advocating this view, carefully removed it with a pair of delicate forceps, and in doing so extracted the little piece of capsule now on the slide. The recovery of the patient was without any reaction.

DR. KNAPP added that the main danger adhering to the methods of extraction which are combined with an iridectomy, arose from pieces of iris and lens capsule remaining lodged in the wound and causing inflammation. To remove the iris was easy enough, since its intrusion into the section could be more readily detected than that of the capsule, which, on account of its tenuity and transparency, might be invisible. He therefore made it a rule not only to cleanse the wound most carefully with delicate forceps, but to pass a blunt spatula through it in order to push eventual pieces of capsule and iris back into the anterior chamber. To demonstrate the severe reactive processes which were engendered by the imprisonment of capsule in the wound, DR. KNAPP showed the corresponding pictures in *Prof. O. Becker's* and *Drs. Genth and H. Pagenstecher's* atlantes of the pathological anatomy of the eye, two recent works of great merit, and of which that of Genth and Pagenstecher, by its superb execution, was an ornament to the medical literature.

## New Instrument.

### DESCRIPTION OF A NEW INHALER FOR CHLORIDE OF AMMONIUM.

THE importance of chloride of ammonium, as a therapeutic agent in the treatment of catarrhal affections was long ago recognized by Profs. Fuchs, Lassègue, Geiseler, Lewin, Elsberg, Cohen and other eminent medical men, but the methods of generating the vapor were so unsatisfactory that they could not be introduced into general practice.

The first real practical method of generating and applying the nascent chloride of ammonium, although attributed to Lewin, was, I think, devised by Prof. Louis Elsberg, of New York. He employed three bottles, two of them having each a tube extending through the stopper to the bottom of the bottle for the admission of air, and a short tube passing simply through the stopper as an exit for the vapor. These exit-tubes were each connected with a long tube extending to the bottom of the third bottle. This bottle had also a short tube passing through the stopper for a mouth-piece.

The first two bottles contained respectively ammonia and muriatic acid, the third water. Suction upon the mouth-piece combined the two vapors in the third bottle. This instrument fulfilled the purpose for which it was designed admirably; the only objection to it was that it was cumbersome, not portable, and could not be prescribed by physicians in general practice. To overcome these objections, several instruments have been devised, having the same principle embodied in one bottle. They are nearly all open to the following objections: the acid-holder is too small, generally holding only a few drops of acid, and having to be replenished every time it is used. The acid-

holder is open, allowing the escape of vapor when not in use, and spilling the acid or mixing it with the ammonia, when tipped or inverted. The current of air during aspiration upon the mouth-piece merely passes into the mouth or over the top of the acid-holder, and does not become impregnated with sufficient vapor to make dense fumes of ammon. chlor. They are easily broken, complex, and difficult to manage.

I have constructed an instrument which obviates all of these objections, being at the same time simple and compact, as will be seen by the accompanying plate and description.

*a*, acid-holder, having a tubular neck passing through the stopper and provided with a tube, *d*, fixed in the bottom. This tube serves as an outlet for the acid vapor and prevents the mixing of the hydrochloric acid and ammonia. The acid-holder will contain sufficient acid to last for several days, and admits of a small-necked bottle with a tightly fitting rubber stopper, which can be easily removed without danger of breaking the acid-holder or exit-tube; *c*, short piece of rubber tubing stretched over the neck of *a*, for packing; *b*, tube passing through the neck into the acid-holder. This tube can be adjusted at any desired height, where it is held by the packing, or removed for the purpose of emptying the contents of the acid-holder; in connection with the packing it prevents the escape of acid when tipped or inverted, and of vapor when not in use. With this combination the acid-holder is to all intents and purposes hermetically sealed, and may stand for an indefinite period without loss of vapor. The tube *b* serves the double purpose of a funnel for the acid and of directing a current of air against or through the acid when in use. By this means the acid is all utilized, and the current of air passing through the acid-holder thoroughly impregnated with acid vapor, and as dense fumes of chloride of ammonium produced as desired.

To generate chloride of ammonium the acid-holder is filled from  $\frac{1}{2}$  to  $\frac{3}{4}$  full of C. P. muriatic acid. The bottle

is  $\frac{1}{2}$  full of water, to which a sufficient quantity of aqua ammonia is added. Suction upon mouth-piece *c* combines the vapors of ammon. and muriatic acid in *b*. Almost any agent can be used in combination with the chloride of ammonium by adding it to the ammonia sol., or alone by dispensing with the ammonia and acid.

In the treatment of aural catarrh, the Eustachian catheter can be used by attaching it to the flexible tube, and attaching a hand-bellows to a tube without a flange, substituted for *b*, when the vapor can be carried to the desired part.

The hand-bellows can also be used in case of young children, and the vapor simply blown into the face where it must be inhaled.

L. E. FELTON, M.D.

POTSDAM, N. Y.

ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from Dec. 2 to Dec. 8, 1877.*

WATERS, W. E., Capt. and Asst. Surgeon. To accompany battalion 2d Arty. from Carlisle B'ks., Pa., to Texas, and on completion of this duty report in person to Comd'g General Dept. of Texas, for assignment. S. O. 246, A. G. O., Dec. 5, 1877.

LORING, L. Y., Capt. and Asst. Surgeon. Leave of absence extended five months. S. O. 243, C. S., A. G. O.

PATZKI, J. H., Capt. and Asst. Surgeon. Granted leave of absence for six months with permission to go beyond sea. S. O. 243, A. G. O., Nov. 30, 1877.

DICKSON, J. M., Capt. and Asst. Surgeon. Assigned to duty as Post Surgeon at Fort Klamath, Oregon. S. O. 171, Dept. of the Columbia, Nov. 20, 1877.

TURRILL, H. S., 1st Lieut. and Asst. Surgeon. Having reported from leave of absence, assigned to duty at these Headquarters. S. O. 201, Dept. of Texas, Nov. 30, 1877.

HALL, W. R., 1st Lieut. and Asst. Surgeon. Assigned to duty as Post Surgeon at Fort Stevens, Oregon. S. O. 168, Dept. of the Columbia, Nov. 15, 1877.

DR. EDWARD H. CLARKE, of Boston, Mass., died Nov. 30th, of cancer of the rectum, in the 57th year of his age. He graduated at Harvard in 1841; at the medical department of University of Penn., in 1846. In 1850 he and others started the Boylston Medical School, and in 1855 he was appointed Professor of

Materia Medica in the Harvard Medical School, which position he held until 1872. He was an interesting and popular writer, but he will be principally known by his essays on Sex in Education, and his paper on Practical Medicine in the Century of American Medicine. He was a very successful lecturer, and had the reputation of making "materia medica interesting."

**MILITARY SURGERY IN TURKEY.**—The following details will seem incredible to those who are not acquainted with the peculiar ways of the Turkish administration. An artilleryman had his knee shattered at Sistova by the explosion of a shell, and after his wound had been temporarily dressed he was transported from the field of battle to Constantinople. In spite of his intense sufferings, he listened with the greatest interest to all the news from the seat of war. On his arrival in Constantinople, amputation was found to be necessary; but before the operation could be performed, permission had to be obtained from the ministry of war. This permission must always be obtained before an amputation can be performed in a Turkish hospital, and it not unfrequently happens that the patient dies before the civil functionaries have ceased deliberating on the demand of the surgeons. Fortunately for our artilleryman, his case was pushed through with exceptional rapidity, and the desired permit was given after a delay of only eight or ten days. The brave soldier, who had awaited the pleasure of the administration with the most exemplary patience, bore the operation with heroic courage; there is still hope that his life will be saved.

**HEREDITABILITY OF THE WHITE LOCKS OF HAIR ON THE FOREHEAD.**—Dr. Rizzoli knew a young girl who had a long, thick lock of perfectly white hair on the forehead, the rest of the hair being a very pronounced black. This anomaly had been congenital and hereditary in the girl's family for two centuries. Whenever it existed in a parent, several of the children were certain to present it. The genealogical tree of the family could be traced back for six generations, including about forty-five persons, more than half of whom presented the white tuft.

**AN UNHEALTHY CELLAR.**—A correspondent of the Massachusetts State Board of Health gives a sketch of the cellar of a house in Hadley, built by a clergyman. It was provided with an open well and sink drain, with its deposit-box in close proximity thereto, affording facility to discharge its gases in the well as the most convenient place. The cellar was used, as country cellars commonly are, for the storage of provisions of every kind, and the windows were never opened. The only escape for the soil moisture and ground air, except that which was absorbed by the drinking water, was through the crevices of the floor into the rooms above. After a few months' residence in the house, the clergyman's wife died of fever. He soon married again, and the second wife also died of fever within a year from the time of marriage. His children were sick. He occupied the house about two years, and was succeeded by a man named B——. His wife was soon taken ill, and barely escaped with her life. A physician then took the house! He married, and his wife soon after died of fever. Another physician took the house, and within a few months came near dying of erysipelas. He deserved it. The house meanwhile received no treatment; the doctors, according to their usual wont, even in their own families, were satisfied to deal with the consequences, and leave the causes to do their

worst. Next after the doctors, a school-teacher took the house, and made a few changes "for convenience," apparently, for substantially it remained the same, for he, too, escaped as by the skin of his teeth. Finally, after the foreclosure of many lives, the sickness and fatality of the property became so marked that it became unsalable. When last sold, every sort of prediction was made as to the risk of occupancy; but, by a thorough attention to sanitary conditions, no such risks have been encountered. And this, too, could be matched by a number of city houses which have fallen under our observation. One we knew of on Brooklyn Heights, and not long ago, notorious for its unhealthfulness. *It was built over an old priory vault!* And only a few weeks ago a clergyman, Rev. Mr. Crowthers, and four children, were killed by the pent-up poisonous air of a Brooklyn cellar. Many we know of in both New York and Brooklyn, built in ground filled in with street dirt, ashes and house garbage; palatial some of them are, in both dimensions and appointments; but the leprosy which cleaved unto Gehazi for his too great haste to get rich was not more pertinacious than that which is fastened to these dwelling-places, erected under the same propensities as those which governed him.—*The Sanitarian.*

**STATISTICS OF SUICIDE IN FRANCE IN 1876.**—During the year 1876, 4,435 men, and 1,132 women committed suicide in France. In the Department of the Seine alone there were 915 suicides, while the number did not exceed 100 in any of the other departments. Death was caused in 2,472 of the cases by hanging, in 1,514 by drowning, in 893 by firearms, in 407 by the inhalation of the fumes of burning charcoal, in 129 by poison, and in 154 by precipitation from lofty buildings. Thirty-one individuals threw themselves under railroad cars, one fireman threw himself into a furnace, and one man had recourse to castration. Of the suicides, 1,946 were unmarried; 29 were under 16 years of age, and 98 were over 80 years of age; 1,828 were peasants, 1,038 belonged to the working classes, 228 were domestics, 987 belonged to the liberal professions, and 241 were engaged in business. Among the causes which led to the self-murder, the most frequent was drunkenness, which counted 1,433 victims; 798 persons killed themselves because they were afflicted with incurable diseases; 633 on account of domestic troubles, and 320 from dread of poverty.

**AN ANCIENT WINE.**—H. M. Berthelot recently analyzed the contents of a small glass vase that had been found in the environs of Arles, and belonged to the Museum of Marseilles. The vase consisted of two ampullae communicating with one another, and it had been sealed by fusion. The capacity of the vessel was about thirty-five cubic centimetres, and it contained about twenty-five cubic centimetres of a yellowish liquid which had a strongly vinous and aromatic smell. Its taste was hot and strong, on account of the presence of alcohol, acid, and aromatic matters. The analysis showed only forty-five cubic centimetres of alcohol, and three grammes of fixed acid to the litre (1,000 c.c.). There were only traces of sugar, a proof that the wine had not been sweetened. This phial of wine was found in an ancient burial-place, and had probably been placed there as a pious offering to the manes of a deceased friend. It is a curious relic of the past, and is especially interesting as affording evidence of the composition of one of the wines manufactured fifteen or sixteen centuries ago.

### CLINICAL LECTURES.

DELIVERED AT THE COLLEGE OF PHYSICIANS AND SURGEONS, N. Y.

By PROF. T. GAILLARD THOMAS, M.D.

(Reported by P. BRYNBERG PORTER, M.D.)

- I. ABDOMINAL PREGNANCY, ITS DIAGNOSIS AND TREATMENT.
- II. INJURY FROM PESSARIES.
- III. PROCIDENTIA UTERI.

#### I.—ABDOMINAL PREGNANCY, DIAGNOSIS AND TREATMENT.

GENTLEMEN:—The chief interest of the first case which I present to you to-day lies in its history, and to this I invite your careful attention. The patient's name is Eliza R. She is a colored woman, a native of the United States, and twenty-four years old. She has been married four years, and has had one child, but no miscarriages. The child was born within a year after her marriage, and she says she became pregnant a second time about the last of June, 1876. Being acquainted with the evidences of pregnancy by experience, she was not likely to be mistaken, and she tells us that her menses stopped, nausea ensued, the abdomen began to increase in size, the breasts became swollen and secreted milk, and she had longings for unusual things, as had been the case previously when she was pregnant. In October (just a year ago), she says quickening occurred. At first motion was very indistinct, but afterwards became very marked. The child's movements were plainly visible, and there can be no reasonable doubt on this point, as the husband, who is an intelligent man, observed them also.

About the first of April last, labor came on, and you will note that this was the regular time for the normal close of gestation. She had previously engaged a physician to attend her, and also the services of a nurse. She was taken sick on a Sunday, and the pains were weak and rather high up; occurring about every ten or fifteen minutes, as near as she can remember. The doctor came to see her twice that day, and told her that he did not think labor would come on just then. Strange to say, it has not occurred up to the present time. He called again on Monday, and then on Tuesday; and on Tuesday night the pains left her entirely. Since that time her health has been gradually improving, and now she is able to attend to all her duties, and seems quite well.

She comes to us to-day feeling thus; yet there are about her all the appearances of a large abdominal tumor filled with fluid. By palpation the most distinct fluctuation is obtained, and there is every sensation about the mass of a large ovarian cyst. If there had been no history, such as we have heard, I should have undoubtedly pronounced it of this character. In addition to the sense of fluctuation given by it, we find that the percussion-sound is quite flat everywhere over its surface. Placing the patient on the back, I employed conjoined manipulation in order to make out the size, shape, and position of the uterus, and to discover whether there were any growth of any kind connected with it; and ascertained that the uterus lay directly under the tumor, and was somewhat larger than normal. Afterwards the probe

was inserted into the uterine cavity, and it was found to measure three inches. Now, what is our diagnosis? Excluding various other conjectures, we have at last to differentiate between two conditions, either of which would account for the presence of an abdominal tumor presenting such characters as have been above described. These are ovarian cyst and abdominal pregnancy. Eighteen months ago a lady was sent to me by a physician of this city whose case was precisely like that of our patient here, with the exception that her general health was depreciating very rapidly. She was suffering from hectic fever, her temperature averaging about 102 degrees, and she presented the appearance of a person in the advanced stages of phthisis or diabetes mellitus. I could make no positive diagnosis, but as the patient gave such a clear history, I at once determined to employ the aspirator, in order that I might be enabled to do so. By means of this instrument I drew off about a gallon of fluid, which was of a sero-purulent character, very much like that seen in empyema, when the formation of pus has not gone on very long in the pleural sac. After the removal of the liquid I found remaining a solid mass of about the size of a fœtus at full term, and had not the slightest difficulty in making out the different parts of the child through the abdominal walls. Believing that an operation offered the only chance of saving the patient's life, I made an incision with the bistoury, and finding the fœtus lying loose in the peritoneal cavity, extracted it by the feet. Curiously enough, there were no peritoneum, intestines, kidneys, or ovaries to be found, for everything was completely plastered over with inflammatory lymph. The child was a male, and weighed seven pounds. After inserting a drainage-tube, I sewed up the wound, and from that time the patient began to improve, until she eventually became entirely well. A short time ago she called to see me, and I utterly failed to recognize her, so robust had her health become. I have related this case to illustrate the one now before us. The question is, whether we have to deal with an ovarian tumor or abdominal pregnancy, and I would caution you not to confound the latter with tubal pregnancy. I have not the slightest doubt in my own mind that the second of these two conditions is present, but I will not be able to determine it positively to-day, for the reason that the patient resides out of the city, and as it is necessary for her to return home immediately, it will be impossible to make use of the aspirator on this occasion. One very valuable point in the diagnosis of pregnancy, you know, is the recognition of the body of the fœtus floating in the liquor amnii. But here the trouble is that there is entirely too much fluid, which we may call pseudo liquor amnii. We cannot, therefore, decide positively in such a case until we have drawn off a portion, at least, of this; but with the aid of the aspirator we could arrive at a certain diagnosis in a few minutes, since it would enable us to feel distinctly the head, trunk, and limbs of a fœtus, if one were present. Circumstances, however, will not admit of its use to-day, as I have just explained.

There is one unfortunate point about this case, and that is of a moral nature, viz., the patient is fully convinced that she is getting well; and it will be no easy matter to persuade her that she is really in great danger. Suppose, first, that she has an ovarian cyst. The ordinary course of this affection takes about three years, and then the patient dies, unless something is done for getting rid of it. If, on the other hand, the case is one of abdominal pregnancy, the presence of the fœtus will change the character of the peritoneal

fluid, so that, instead of being bland and innocuous, like that seen in ascites, it will become a source of contamination and death. An immense abscess, a huge mass of pus, will be found; and if suppuration once occurs, the chances will be all against our patient. If, however, an operation should be undertaken now, the prospect would be decidedly favorable; for the chances would be as good at least as in the case of the removal of an ordinary ovarian tumor. There is one point about the operation which I wish to particularly impress upon you, and that is, not to remove the placenta in such cases as this. Why not? Because your patient would probably bleed to death if you did. In the case in which I operated, as I have described to you, I found the placenta, but I left it *in situ*. By means of the drainage-tube a way was provided for its gradual coming away. In abdominal pregnancy the case is very different from that of natural utero-gestation, where, after the removal of the fœtus, living ligatures are supplied for the bleeding vessels by the contraction of the uterus. In another case of extra-uterine pregnancy in which I operated I nearly lost my patient from hemorrhage, because I attempted to remove the placenta. This was one where the product of conception had become developed in the Fallopian tube, and I made the incision through the walls of the vagina. When the placenta was almost half detached, the patient was so exhausted by a sudden and profuse gush of blood, that the gentleman who was assisting me exclaimed that she was already dead. She rallied, however; but on the fourth day afterwards my assistant found that her temperature was 104 degrees, and on making an examination, discovered a part of the placenta in the tube which had been left in the sac. Through it he succeeded in removing the whole mass, and after that the patient made a good recovery.

A number of years ago, a country doctor practising on the island of Edisto, off the coast of South Carolina, on being called to a case of labor, found the child's head pressing upon the vaginal wall, outside of the uterus, and recognized it as a case of abdominal pregnancy. Cutting through the intervening tissues with the knife, he applied the obstetric forceps, and delivered a living child, and the mother afterwards recovered. This is one of the few cases of this character on record in which the child has been born alive. Within the last three years, in England, another living child was delivered by means of an abdominal incision. In the present case, however, it is unfortunately too late to hope for like success. The fœtus probably died about the time that the so-called labor took place. Why it should have done so I am at a loss to say, but this is the ordinary rule in such cases. In the one where I operated the fœtus died at eight months, and the cause of its death was a very curious one. A long hair was found wound tightly around the umbilical cord. It was probably a giant hair which had grown upon the head of the child, though, strange to say, its scalp seemed remarkably free from hair. If left to herself, I am quite sure that this patient would not come near us again, but as she was sent here by a medical friend, who has charge of her in the town where she resides, I trust that he will be able to persuade her to submit to an operation. At all events, we will be enabled to keep track of the case.

#### II.—A CASE OF INJURY FROM PESSARY.

Mrs. Frederika S—, aged thirty-six, and a native of Germany. Has been married six years, and has had two children, but no miscarriages. The last child was born a year ago. She says that she was well

up to a few months ago, since which time "her womb has been troubling her," and that two months ago a supporter was put in by a physician. To-day she came here suffering intensely from pain in the back, abdomen, and limbs, and with a very profuse and offensive purulent discharge, like that of acute gonorrhœa, pouring from the vagina. On making an examination, I found in her vagina the anteversion pessary I now show you, which has a movable arm, and is called mine, but which I have long since discarded. Even if I still did use an instrument of this construction, I should never think of introducing one of the extremely large size of that taken from our patient. Now, I want to put you on your guard against the improper or careless use of pessaries, and particularly those designed for the relief of anteversion; and the present case will serve as a good commentary upon this remark. A two months' sojourn of the pessary in the body has resulted in completely cutting through the vagina. It was found deeply imbedded in the walls of the latter, and could only be removed with considerable difficulty. Great furrows were found at the points where the instrument pressed, and the bladder itself was nearly cut through in one place. The points that I desire to make here are these:

(1) Always put in a pessary that is perfectly movable when it has been adjusted, or it will undoubtedly cut into or through the vagina.

(2) Never leave any anteversion pessary in the vagina for two months at a time.

(3) Never introduce any kind of a pessary which the patient cannot take out herself. She should always be instructed as to the way of doing this, or else pelvic cellulitis or other serious trouble may possibly be set up before she applies for medical aid.

There are two other points in connection with this case to which I will direct your attention before dismissing it. The first is—anteversion pessaries are much more apt to give rise to trouble than retroversion instruments. In one month longer this patient would probably have died if the pessary had not been removed. Cellulitis seemed to be just about commencing, and if she had not suffered from this, vesicovaginal fistula would, no doubt, have occurred. Such a result might occasion a great deal of trouble, not only in the way of treatment, but also from a medico-legal point of view; for your patient might fall into the hands of an unfriendly practitioner, who would incite her to seek redress at a court of law. Still more awkward might be your position if there should be a fatal issue to the case. The second point is—when you are called upon to remove a pessary, and find that it has cut through the vaginal walls, never make any reflection upon the physician who introduced it. In case you do, the tables may be turned upon you at no distant date, for these accidents may occur at any time to even the most careful men in the profession. For instance, you may tell your patient to come back to you in one week, warning her of the danger which may result from neglecting to do so; and yet you may see or hear nothing more of her for a year, when you are perhaps informed of the injury which your pessary has done her. Very likely the condition of affairs which we have found in the present case has resulted in this manner. The same remark holds good in regard to almost any sort of a contrivance, however extravagant, which you may find about a patient's vagina.

#### III.—PROCIDENTIA UTERI.

Mrs. Margaret M—, a widow, fifty-five years of

age, and a native of Ireland. She has had six children, but no miscarriages. The last child was born thirteen years ago, and her husband has been dead for five years. She says that she enjoyed good health up to one year ago, when she began to have a little soreness across her. This is all that she complains of, except that she mentions rather incidentally that her womb comes out. Now, the extraordinary thing about this case is, that with almost absolutely no symptoms, the uterus is completely out of the vagina. Even the fundus may be considered practically out of the body. In contrast to this, a woman may have an apparently slight flexure of the uterus, and yet suffer intensely with a fixed pain in the back, dysmenorrhœa, hysteria, and all sorts of complaints, on account of the interference thus caused to the circulation. This woman is now suffering from complete prolapsus of the uterus; but, contrary to the usual rule, she has had but little trouble before the organ reached this stage. In the first stage of prolapsus the patient ordinarily suffers intensely, and is scarcely able to walk, on account of the tension upon the uterine ligaments. In the second stage she has still considerable suffering, though not so much as before; but in the third stage there is usually no pain whatever, because the uterine ligaments, as a result of the long-continued traction upon them, have been completely worn out, and can now make no further resistance.

On making an examination in this case, we find that the bladder and rectum have both been pulled out of the body with the prolapsed uterus. The latter organ is not large, having undergone the atrophy which always follows the menopause; but there is an extensive laceration of the cervix. The history of the case has been, no doubt, somewhat as follows: When the last child was born, the head caused the rupture of the cervix, and afterwards tore away almost the entire perineum. After the labor was over, retrograde metamorphosis was interfered with in the uterus by the injury to the cervix, and subinvolution resulted. As a result of the rupture of the perineum, there was also subinvolution of the vagina, and on account of this removal of the triangular perineal body, the shape of the posterior wall of the vagina was changed from that of the letter C to that of the letter S. In the normal condition of the parts the posterior wall, by means of the tissues beneath it, resting upon the firm coccyx, forms a strong spring, as it were, shaped like those of the old-fashioned coach, for the support of the uterus and the anterior wall, which, with the bladder, ordinarily presses directly upon it. Accordingly, after the removal of the perineal body, the lower part of the S acted inversely to the upper part, and the uterus, enlarged and heavy, began gradually to descend, its prolapse being accelerated by the pressure of coughing, defecations, and other actions. Then the bladder, having nothing to rest upon, also began to descend. But the uterus and vagina were falling down not only on account of their own increased weight, but also by that of the feces which accumulated in the pouch formed by the anterior wall of the rectum, slipping down with the posterior wall of the vagina. After a time it became impossible to completely evacuate the bladder either, on account of its having descended with the anterior wall of the vagina; and then ammoniacal degeneration of the residual urine took place, giving rise to continual irritation, and causing still further trouble by the straining which it occasioned in the effort to void it. It was near the menopause, and the uterus began to undergo atrophy; but notwithstanding its smaller size, it could

not resist such traction as was made from below by the rectum and bladder. After battling as long as it could, it had to give up the struggle; but it seems to have taken twelve years to get it completely out of the body.

The causes of prolapsus may be summarized under four heads:

(1) Pressure from above. Last year, a girl nineteen years of age, presented herself at this clinic, with the uterus completely prolapsed. She was perfectly virtuous, as was shown by the condition of the hymen, and the procidentia was the result of an accident. The pressure caused by the sudden lifting of a heavy tub of water occasioned it. The physician who attended her at that time made no examination, and treated her for inflammation of the bowels, and the condition had existed for a year when I saw her.

(2) Anything which increases the size and weight of the uterus, such as subinvolution, fibroids, etc.

(3) Anything which diminishes the uterine supports, such as rupture of the perineum and subinvolution of the vagina.

(4) Anything dragging upon the uterus from below, such as prolapsus of the rectum and bladder, fibroids, etc.

The third and fourth class of causes were the principal ones concerned in this case.

The time is not distant when confinement cases will be treated very differently from what they are at the present day. This is a subject of the utmost importance. There is the most urgent need of a radical change in the practice of the majority of the profession, and the time is ripe for the appearance of a stirring and able paper on "The Proper Management of Natural Labor," which will awaken medical men to a sense of their duty in obstetrical cases. The physician should be expected and required to visit his patient from time to time all through her pregnancy, in order to see that everything is progressing favorably for a successful delivery, and to remove, if possible, any condition (such as albuminuria, for instance) which is likely to interfere with this; and I am fully convinced that it will not be long before the accoucheur who does not pursue this plan will be held culpable. Again, he will be held equally culpable if he discharges his patient at the ninth day or the end of a fortnight, without making a physical examination, to ascertain that the parts have sustained no injury from the strain and pressure of parturition, and that the process of restoration to their normal condition is going on satisfactorily. A little attention paid at that time will often prevent the most serious consequences in the future. If the physician had made such an examination in this case, and had found the cervix lacerated, he might have waited a month, and then ascertaining that trouble was resulting from it, he should have sewed it up, and also restored the perineal body, which had given way. The repairing of the injured parts would not have been difficult, and all future evil would have been avoided. The operation of perineorrhaphy would have changed the shape of the posterior arch of the vagina from an S to a C, or rather restored the arch, which had been destroyed; and would have afforded it support once more upon the unyielding sacrum. The bladder also would have been held up in place by its normal support, since the anterior wall of the vagina always rests mechanically upon the posterior wall. All this could have been readily done in the second month after delivery, and it would certainly have been a great deal better to do it then than to wait thirteen years before undertaking the operation. It is true that this woman has suffered

comparatively little pain and inconvenience in consequence of the neglect of her physician; but this is a very rare exception to the general rule, and, as I said before, the time is not far distant when the medical man will be held responsible for allowing such a condition to continue without interfering to prevent the evil results so sure to follow from it.

## Original Communications.

### RARE FRACTURE OF SUPERIOR MAXILLA,

WITH FRACTURE OF ONE NASAL BONE, CONTUSION OF THE EYEBALL, AND DOUBLE RUPTURE OF THE CHOROID.

By CHARLES S. BULL, M.A., M.D.,

SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY AND TO CHARITY HOSPITAL.

In No. 356 of the Record, for Sept. 1, 1877, I reported three cases of old injury, in which the facial bones had been fractured, the nasal duct obliterated, and the eyeball either entirely destroyed or seriously injured. In two of these cases the original injury had occurred two years, and in the third case two months, before I saw the patient. Hence, the only course left for the surgeon, the nasal duct being in all three obliterated, was destruction of the suppurating lachrymal sac. In No. 364 of the Record, for October 27, 1877, is the report of an exceedingly interesting case of severe injury to the face, with compound fracture of the nasal bones, fracture of the nasal process of one superior maxillary bone and of the nasal spine of the frontal bone, and destruction of the eye, by Dr. John D. Neet, of Versailles, Kentucky. Dr. N. was fortunate enough to see his patient within an hour after the injury, and to his prompt recognition of the importance of endeavoring to elevate the depressed bones, and thus prevent deformity, is due the recovery of the patient with a perfectly patent nasal duct. The report of the case and the treatment followed is exceedingly clear, and well worth perusal.

As an additional contribution to the subject of injuries of the face, the following case of rare fracture of the superior maxillary bone is presented in detail.

*Case.*—The patient, *et.* 30, a bartender, was first seen by me on January 11, 1877. Three days before he had been struck a violent blow on the left eye with a heavy glass bottle, which knocked him down, closed his left eye, and caused severe laceration of the soft tissues round the orbit, and copious hemorrhage. When I saw him, the swelling of the lids had subsided considerably, and there was a lacerated wound of the lower lid at the junction of the middle and inner thirds, extending through the entire thickness of the lid, and down for about half an inch upon the cheek. This laceration was situated just at the nasal side of the infra-orbital foramen. The left nasal bone was fractured along the line of the naso-frontal suture, separated from its fellow of the opposite side, and slightly depressed. There was no fracture of the nasal process of the superior maxillary bone, but there was a long vertical fracture of this bone, just in the line of the lacerated wound of the lid, extending from the orbital margin nearly to the alveolar arch. The inner fragment was depressed, as nearly as could be made out, about a quarter of an inch. There was

extensive subconjunctival extravasation, the anterior chamber was full of blood, and the patient had faint perception of light. There was no rupture of the eye, and it was freely movable in the orbit. No injury to the upper lid, and none apparently to the nasal duct. The edges of the laceration in the lower lid and cheek were freshened and brought together by silk sutures, the sutures being passed through the entire thickness of the tissues; an attempt was then made to elevate the depressed nasal bone by cutting down upon it along the line of union with the superior maxilla, and this succeeded. But when a similar attempt was made through the same wound to bring the depressed superior maxilla into place, it failed completely. The fracture did not extend to the alveolar margin, so far as could be ascertained, and there was no sign of any depression in the mouth or pharynx. The inner fragment was firmly fixed in its depressed position, while the outer fragment yielded readily to the pressure of the finger. Attempts at reduction were then abandoned, particularly as there was no deformity perceptible after the wound in the lid had been closed. Cold-water dressings were applied, a four-grain solution of the sulphate of atropia was instilled every hour, and the patient kept in bed. The swelling rapidly subsided, the wound in the lid and cheek healed completely within forty-eight hours, and the sutures were then removed. On the fourth day the blood had disappeared from the anterior chamber, and there was then seen a discolored iris, posterior synechie at the temporal and inferior margins of the pupil, the latter irregularly dilated, and the vitreous was full of blood. The improvement was rapid, and three weeks after the injury the vitreous was sufficiently clear to admit of the fundus being seen with tolerable distinctness. The choroid was ruptured through the macula, the rupture being of the ordinary irregularly crescentic shape, with its concavity towards the papilla. One week later, on the nasal side of the disk, and distant from it about two diameters, was seen another rupture of the choroid, though not complete. The solution of continuity was through the inner layers of the choroid, leaving the outer layers with the larger vessels intact, and across this exposed red network of vessels ran a branch of the central retinal artery. This rupture was also crescentic, with its concavity towards the disk, and was not quite so long as the one on its temporal side. All swelling had entirely subsided both in lid and conjunctiva, and a careful digital examination of the orbit being made, the line of fracture could be traced backward through the orbital plate of the superior maxillary bone, as far as the finger could reach. The inner fragment was still immovable, but the outer fragment could be moved in a direction downward and backward, and no pain was occasioned by its motion. There was no deformity caused by the injury to the bone, but the cicatrization in the lower lid had produced some eversion of the lachrymal puncture, due to the lower end of the cicatrix being adherent to the underlying bone. To remedy this the lower canaliculus was incised and the incision prevented from healing by the daily introduction of a probe. The probe passed readily to the bottom of the nasal duct, showing that no obstruction or obliteration had been caused by the injury.

The lens was not dislocated and remained perfectly transparent throughout. The posterior synechie were broken by the atropia, and the pupil became normal in shape and size, and freely movable. Two months after the injury the patient had vision =  $\frac{20}{200}$ , which could not be improved by any glass.

The interesting features in the case are three in number.

1st. The vertical fracture of the superior maxillary bone, the line of fracture extending for some distance into the orbital floor. As before stated, fractures of this bone are almost always more or less horizontal, the line of fracture running below the malar bone. Though the break ran so near the infra-orbital foramen, the infra-orbital nerve seems to have escaped injury. How the blow was struck is not certain, though it must have come from above downwards, with possibly a slant inward towards the median line.

2d. The double rupture of the choroid, on both sides of the optic disk, and at about the same distance from it, in all senses symmetrical, except that in one all the layers of the choroid were not involved. The exact mechanism of such a rupture is not as yet perfectly understood. It is probable that at the moment of receipt of the injury the ciliary muscle was strongly contracted, but why this should make the choroid more brittle, as it were, and why the rupture should occur at just this spot in the region of the macula, have never been fully explained. A single rupture of the choroid is not very uncommon, but a double rupture in the same eye is a rare accident.

3d. The escape of the lens from all injury. The suspensory ligament of the lens is a very delicate structure, and it is scarcely reasonable to suppose that it would resist such extreme violence as a heavy blow directed full upon the eye, even though the force of the blow may be broken by the margin of the orbit; and yet it is not so very uncommon to meet with such cases. On the other hand, the lens has been known to be dislocated by very slight violence, and even to become opaque from concussion of the head or body. In this case not only was the lens not dislocated, but it remained transparent, and the two images of a candle flame could be distinctly made out on its anterior and posterior surfaces, when the candle was held in the ordinary way.

The other eye remained sound throughout, never showing at any time the slightest amount of sympathetic irritation.

47 EAST 23D ST., N. Y.

### SUBMUCOUS LIGATION OF HEMORRHOIDS.

By R. W. ERWIN, M.D.,

BAY CITY, MICH.

OF the many methods of treatment proposed in this troublesome affection, I do not remember having seen published the operation by submucous ligation. It has been suggested in external hemorrhoidal tumors having a covering of skin, or skin and mucous membrane, but not in the internal form. The procedure causes very little pain during the operation or subsequently. As a rule, no anæsthetic is required, nor is it necessary to put the patient to bed afterwards, or shut him in the house in ordinary cases. It is well known that the hypodermic syringe, after passing through the skin, causes scarcely perceptible pain in its transit through the cellular tissue, except it pierce a vein. As with the skin, it is the mucous membrane that is especially sensitive in this locality, the submucous tissue being comparatively free from sensibility. Of course both are modified by the pathological condition somewhat.

Acting upon this fact, the operation is performed

as follows: the best time is the morning, just after evacuation of the bowels, which may be assisted by the co. licorice powder taken the night before, or an enema previously. The motion of the bowels will generally from the straining bring down the tumors. After washing, the patient is ready, and may be put in the usual position. The tumor should not be seized with forceps or hook, as it causes pain and irritation. Take a straight needle, or one with moderate curve at point, armed with a small, lightly-twisted waxed thread. With or without forceps pass it through the mucus tissue near the base of pile, and carry the needle around beneath the mucous membrane and out at the point of entrance. Tie it sufficiently tight to arrest the circulation, leaving a half-inch or inch of one end of the ligature. It will often be found advisable to carry the needle out through the mucous membrane at one or more points in making the circuit, but care should be observed to enter again at the place of exit. A little castor-oil or cosmoline may be applied over the parts and the whole returned. The effect of the operation is to cut off the vascular supply to the tumor, causing it to shrink away. The ligature comes away without trouble. Should the hemorrhoid puff up or become very dark after ligation, incise it a little with the scalpel, thus relieving the congestion. Operate upon the largest first. If the patient remains about home, two may be tied at the same time; otherwise one, unless small. After removing one or two of the largest, the smaller often disappear. The bowels are to be kept soft with the licorice powder, if necessary—not used as cathartic. For cleansing, a little warm castile soap-suds may be employed. In cases with heat and inflammation, the first effort should be to reduce it. If there is disturbance of the secretions or hepatic derangement, preface the operation a few days before with a mild corrective. I do not claim originality in this method of treatment.

Dec. 12, 1877.

### FRACTURE OF STERNUM BY MUSCULAR ACTION; ALSO, FRACTURE OF SPINOUS PROCESS OF VERTEBRÆ.

By JOHN T. HODGEN, M.D.,

ST. LOUIS, MO.

OCTOBER 19, 1877. Terence Clark, a native of Ireland, aged 38 years, a hack-driver by occupation, and living at the corner of 10th and Pine streets, while seated upon a banister, at the head of a stairs, lost his balance and fell backward a distance of twelve or fifteen feet, striking with his back or shoulders, or both, on some old hubs and fragments of broken wheels.

For a short time after the accident he was unconscious, but upon the return of his senses complained of severe lancinating pain on inspiration, between the shoulders and on the front of his chest. In addition, there was a constant, aching pain, more or less diffused over the entire chest, resulting from the contusion.

Upon each inspiration—if at all full drawn—crepitation could be distinctly felt at the junction of the manubrium with the gladiolus, and also distinctly felt upon manipulation of the spinous processes in the middle dorsal region. The sternum had been fractured at the junction of the manubrium with the gladiolus, and also the spinous process of the sixth or seventh, or both dorsal vertebræ, by the fall.

Movement and inspiration caused the patient much pain. He was dressed with a plaster-jacket, strengthened laterally and in front by strips of sheet-iron. By this means, movement of the osseous framework of the chest was contracted, the breathing became abdominal, and the fractured extremities of bone were put at rest. Ease and comfort soon followed its application.

Nov. 13th.—Bones have united, and patient, to all appearance, is well.

## Reports of Hospitals.

### UNIVERSITY OF PENNSYLVANIA HOSPITAL, PHILADELPHIA.

CLINIC OF PROF. H. C. WOOD, JR., M.D.

#### A RARE CASE—ACUTE MUSCULAR ATROPHY, OR INFANTILE PARALYSIS IN AN ADULT.

On the 8th of August last the patient was walking with a friend through his corn-fields. The weather, though quite warm, was not hot. He suddenly and without any warning felt a very severe pain in his head, followed by dizziness. He did not, however, lose consciousness. He went home and to bed, where he was confined for the rest of the day with fever and vomiting. There was a little blood in the vomit. On August 9th, after passing quite an easy night, he woke up to find that he had lost entirely the use of his right arm. Twenty-four hours afterwards he noted that his left arm below the elbow was also paralyzed, though the paralysis was not complete, there being no loss of sensation. He suffered for the two following weeks with a heavy ache in his right arm, accompanied with slight palpitation and occasional headache, but no fever. There has been a great deal of emaciation and great loss of strength. Three or four days ago he had a slight chill. He thinks that he is getting thinner and weaker every day. There is no giddiness and no indigestion. His bowels are only slightly costive. He tells me that the fever was broken up by the free use of quinia. The attending physician told him that it was an attack of bilious fever. As far as I can gather, his symptoms obscurely simulated those of dumb ague. But the palsy has persisted.

Upon examining his arms more closely, I find no paralysis of sensation. He can only move his right hand, and that but slightly. He has no control whatever over the rest of the arm. There is a pretty fair amount of power in the left arm. The muscles of both shoulders are wasted—the right deltoid to a mere film. I cannot place much confidence upon all the details of the history which the patient brings us, but I am quite sure that there is a very marked palsy here. Now, is this nerve, spinal, or cerebral palsy? It is certainly not a case of cerebral palsy, for, in cerebral palsy there is never such rapid wasting of the muscle. Why do I know this? It is a well-established fact that the muscles of the shoulder, the deltoid, etc., are supplied by nerve-fibres, coming from a number of so-called "trophic" cells situated in the anterior horn of the spinal cord. Such being the case, we are able with assurance to say that the trouble cannot be above the site of these cells. It is therefore certainly not cerebral in its nature. Nor can the palsy be in the nerve-trunks below the cells supply-

ing the muscles. In such case, we could in nowise account for this rapid wasting. Then, too, if there were a local neuritis, there would be extensive pain along the course of the supplying nerves. But walking and jarring gives no pain, and there is no spinal tenderness. There might be disease of the muscles alone, but in that case only one side would be likely to be affected, and, moreover, the wasting of the muscles would not be near so rapid. The muscles have lost their contractility *pari passu*, with the wasting. The faradic current applied to the right arm fails to elicit any response; in the left arm the effect is much more marked, but still far from normal. It might have been an attack of sunstroke, but from all we can gather the symptoms were not by any means those of sunstroke. It is very unlikely that it was an attack of bilious fever, for there was no jaundice, no green vomit, and there is no tenderness over the hepatic region. A clot might be thrown out during the course of an attack of bilious fever, but it would have to be an exceedingly small clot to press only upon these "trophic" cells, and then only upon those supplying one arm. The clot thrown out in bilious fever usually cuts off the motility of the whole, or a large part of one side of the body.

By a careful process of exclusion we are led to the conclusion that the case must be one of acute muscular atrophy, or essential infantile palsy, due to changes which have occurred in the "trophic" cells of the anterior cornu. This is exceedingly rare in adults.

In childhood these "trophic" cells are in the process of active growth; hence, disease, when it attacks them, has a tendency to the acute type. When, however, we come to the consideration of these cells in the adult, we find the case changed. Here the cells have reached and probably passed their period of active growth, and consequently any diseased action which we find located in them has assumed a chronic form. Acute muscular atrophy is essentially a disease of childhood; chronic muscular atrophy, of the adult state. In childhood the process of wasting is exceedingly rapid; the muscle is very soon reduced to the mere shadow of its former size. In the adult the process is a slow one; fibre by fibre and fraction by fraction the wasting goes on. I say that this case of infantile or acute paralysis in an adult is an exceedingly rare one.

The prognosis is very grave, so far as the use of the arms, more particularly the use of the right arm, is concerned. For the disease has reached such a stage that we can do little to check the disintegration of the cells already diseased.

As regards treatment, we must try to strengthen the muscle and keep up its general health by local treatment. If any of the "trophic" cells yet remain healthy, we can try, by proper nerve-food, to keep them up and put a stop to the wasting. Galvanism must be applied locally to the muscles and phosphorus be administered internally. I do not think that strychnia is of much value in these cases. After the acute form of the disease passes off, however, hypodermic injections of strychnia may be made into the body of the muscle. Manipulation of the muscle will also do good. In employing galvanism, that current which causes the most contraction and gives the least pain should be made use of.

#### HYSTERIA.

There are at present two extremely aggravated cases of hysteria in the wards: one, that of a lady in whom the hysteria was brought on by an abortion, and who

has been steadily bed-ridden for seven years. The other case, that of a young girl, I bring before you. She has written out for me what she claims to be a reliable history of her past life, in so far as relates to the cause of her complaint.

According to this strange document, she taught school until she was eighteen, when she went into a clergyman's family as governess. The clergyman seduced her and gave her medicine which produced an abortion. Ever since that time she has been exceedingly nervous and hysterical. When the fits are on her, she states that she *eats glass and lead-pencils, and packs her vagina with broken glass.* Such things have been done before, but I don't know how much of the story to believe in the present case. She seems to be suffering from a chronic ovaritis, which is the probable cause of the hysteria.

Such cases as this one are fit subjects for ovariectomy, if the ovary be proven to be diseased. As regards the first case, stern moral control should be exercised, and the lady should be forced first to sit up in bed, and then to walk.

## Progress of Medical Science.

**NERVOUS HEMOPTYSIS.**—In a series of papers published in the *Archives Générales* for January, February, and March, 1877, M. Carré has sought to decide the question whether the nervous pulmonary hemorrhages that accompany neuropathies, especially hysteria, are the consequences or only accidental complications of the nervous affections. Many physiological and clinical facts, such as the pulmonary hemorrhages after division of the vagus or of the cervical ganglia of the sympathetic, etc., etc., speak for the former view. M. Carré reports 29 cases, which demonstrate the connection between nervous diseases and bleeding from the lungs. The primary affections which caused the bleeding were: in three of these cases, diseases of the cord; in one, multiple cerebral hemorrhages; in ten, hysteria; in one, chorea; and in seven, epilepsy. The number and variety of the above neuropathic conditions are in themselves evidence that there is something more than a mere accidental concurrence of the two affections. The quantity of blood raised varies; sometimes there is only enough to tinge the sputa, and again streams of pure blood may gush forth. The hemorrhage, however, never becomes as abundant as when it is due to tuberculosis. It is frequently accompanied by epistaxis, hematuria, enterorrhagia or cutaneous hemorrhages; also by certain vaso-motor symptoms, such as turgescence of the cutaneous and cervical vessels, distention of varices during hysterical crises, varying paleness and redness of the face in hysteria and epilepsy, circumscribed swellings on the forehead, macular exanthems, punctiform ecchymoses and erysipelatous patches. Physical examination of the chest in M. Carré's cases always gave negative results. In a few of the cases the hemoptyses were followed by galloping consumption.

Like hysteria, "nervous hemoptysis" is much more frequent in women than in men. The attacks generally come on at irregular intervals, except in the neuropathies, which manifest themselves by paroxysms at regular intervals. In these last cases the hemoptyses precede or follow or alternate with the paroxysms, but rarely accompany them. M. Carré does not in-

clude vicarious menstrual hemorrhages among the "nervous hemoptyses."

The author ascribes the pulmonary hemorrhages to a *vaso-motor paralysis*, which is consecutive to the stage of excitation of the vaso-motor centre. Both the neuroses and the organic cerebro spinal diseases produce through the agency of the sympathetic, first a narrowing, and then a dilatation of the vessels; it is when the latter sets in that the hemorrhages take place. Hence it is that the bleeding usually occurs *after*, and only rarely *during* the paroxysms.

The prognosis of nervous hemoptysis depends on that of the primary disease. In itself it is almost never fatal. The most dangerous cases seem to be those in which multiple hemorrhages occur and the sputa are tinged with blood during the intervals.

The treatment must be directed against the primary disease. Astringents are only indicated when the bleeding is excessive. Venesection is usually injurious. Baths and derivatives to the skin are sometimes useful. In the author's experience, arsenic and sulphate of quinine have proved the most useful drugs. They excite directly the contractility of the capillaries, and act indirectly on the cord and the vaso-motor nerves. —*Allg. Med. Cent. Zeit.*, Oct. 17, 1877.

**POISONING BY AGARIC BULBEUX.**—At a recent meeting of the *Académie de Médecine*, in Paris, M. Gubler read some extracts from a paper by M. Oré, on poisoning by the agaric bulbeux, a species of mushroom. M. Oré maintains:

1. That the symptoms manifested during life, by animals that have been fed on this fungus, present by their convulsive character a great resemblance to the symptoms produced by strychnia.

2. That the lesions observed at the autopsy, which consist in more or less marked congestions with ecchymoses, ulcerations, etc., occupying the entire length of the gastro-intestinal mucous membrane, also resemble completely the lesions found in animals which have been poisoned by strychnia.

3. That powdered charcoal has the same effect on a solution containing the deleterious principle of the agaric bulbeux, as on a solution of strychnia. When the two solutions are agitated with the powder, and then filtered, the charcoal retains both the poisonous principles.

4. Finally, that if a solution of strychnia be injected into a vein of one dog, and acidulated water, in which some bulbs of agaric bulbeux have been macerated, into a vein of another, both animals will present absolutely similar symptoms, and will die after the same interval of time.—*La France Médicale*, Oct. 20, 1877.

**BROMIDE OF POTASSIUM IN PUERPERAL CONVULSIONS.**—Dr. Hutchison, of Aberdeen, reports two cases of puerperal convulsions, which were treated by bleeding—in one case general, in the other local—and bromide of potassium. The bleeding was followed by decided improvement in both cases, but this improvement was not continuous. After the exhibition of the bromide, the convulsions became less severe, came on at longer intervals, and finally ceased entirely. Dr. Hutchison is satisfied that the successful issue in these two cases was mainly due to the direct effect of the drug. In one of the cases the bromide was given in twenty grain doses, every two hours, and in the other in fifteen grain doses.—*The Practitioner*, September, 1877.

**LESIONS OF THE CORD IN TWO CASES OF TETANUS.**—Professor Tyson, of the University of Pennsylvania,

reports two cases of acute tetanus, in which the autopsies revealed softening of the posterior columns of the cord. In one instance this was attended by extravasations of blood, chiefly into these columns, but to some extent also from the vessels of the pia mater; also by destruction of the central gray commissure. In the second case, no extravasations were found in the posterior columns, but the macroscopic examination revealed venous congestion of the membranes of the cord, and of the lining of the central canal.

These two cases do not, however, diminish the uncertainty already existing as to the pathology of tetanus. In fact, they tend rather to increase it by adding another to the many lesions of the spinal cord that have been found associated with the disease. They justify the suggestion that, in future, the investigations should be directed to the peripheral nerves, extending from the seat of injury to the nerve-centres, as well as to these centres themselves.—*The Practitioner*, August, 1877.

**THE USE OF PEROXIDE OF HYDROGEN TO PREVENT THE SPREAD OF SCARLET FEVER AND SMALL-POX.**—Since April, 1873, Dr. John Day, of Melbourne, has treated, with the peroxide of hydrogen, 115 cases of scarlet fever, being all the cases of the disease which came under his charge. These cases occurred in eighty-eight different houses, in only seven of which was there any extension of the disease after he had commenced his treatment. Six of the cases died. The treatment consisted at first in free inunctions three times a day, with a preparation composed of one part of ethereal solution of peroxide of hydrogen (erroneously called ozonic ether), and seven parts of pure lard, well incorporated without the aid of heat. The inunctions were continued about three weeks. No other remedies were prescribed except in a few cases in which the throat symptoms were severe, when a gargle, composed of two drachms of the ether in eight ounces of water, was ordered to be used every second hour. In his recent cases, Dr. Day has slightly modified his treatment. He now generally prescribes for the inunctions: ozonic ether, four drachms; pure lard, four ounces; benzoic acid, twenty grains; otto of roses, four drops, to be carefully mixed without the aid of heat. The benzoic acid is powerfully antiseptic, and possesses, moreover, the valuable property of allaying cutaneous irritation. He also prescribes throughout the whole course of the disease, a mixture composed of two or three drachms of ozonic ether in half a pint of water; a dose ranging from a teaspoonful for a child a year old, to a tablespoonful for an adult, to be taken every second hour. This is given to relieve the throat symptoms and to disinfect the breath.

Peroxide of hydrogen contains a larger amount of oxygen than any other known substance, and moreover, one-half of its oxygen is loosely combined, and in a highly active condition, ready to combine with any organic matter with which it may be brought in contact. It would seem, therefore, to be an agent specially suited for the destruction of the poison-germ of scarlet fever, small-pox, and other epidemic diseases. Dr. Day has so much faith in its disinfecting properties, that he recommends its use to disinfect letters, papers, and articles of clothing, over which it should be sprinkled. It may be combined with any perfume, preferably toilet-vinegar, or eau de cologne, in the proportion of about a drachm to the ounce. From a theoretical point of view, it might be supposed that peroxide of hydrogen would act more powerfully as a disinfectant in small-pox than in scarlet fever, in consequence of the curious property that pus-cells pos-

sess, of exalting its chemical activity and giving it the oxidizing powers of ozone.—*Medical Times and Gazette* and *The Practitioner*, August, 1877.

**PROPAGATION OF MALARIAL FEVER.**—At the recent *Congrès Scientifique de Havre*, M. Leadre read a paper on two epidemics of malarial fever, which he observed in the environs of Lillebonne in 1875 and 1876. Intermittent fever is endemic in that valley and in the neighboring marshes, but it is very rare on the table-lands. In 1875, however, he met with several cases in the latter regions which he attributed to the hay which had been brought from the marshes and spread there to dry. The same thing was observed after the hay-harvest of 1876. These observations afford ground for the assumption, that the wet hay was the vehicle of the marsh-poison.—*Union Méd. et Scient. du Nord*, Est., Sept. 30, 1877.

**EXTIRPATION OF THE LARYNX.**—Dr. Foulis, of Glasgow, records the eleventh case in which the larynx has been removed for the relief of disease. This operation was first performed by Billroth in 1873, for cancer of the larynx. Two months after the operation the patient was discharged cured and able to speak clearly, though monotonously, by means of Gussenbauer's tube. Since then various Continental surgeons have performed the operation for relief of malignant disease with varying success. Six of the recorded cases ended fatally; two from the return of the disease at three and six months respectively; two from pneumonia at four and fourteen days; one from gangrene of the lung on the fourth day; and one on the sixth day from collapse, due to shock, insufficient food, and imperfect protection of the trachea from the introduction of blood and secretions. Of the remaining cases, one was a very partial operation for stricture in syphilitic disease, the patient dying eleven months afterwards from the constitutional affection; two have been but partially reported, and the ultimate issue cannot be stated. Lastly, the case published by Prof. Bottini is the only one on record in which, six months after complete excision of the larynx, the patient was in a quite satisfactory condition.

In the present case the disease had been twice removed by external incision, and now extirpation of the entire larynx was decided upon as the only means of affording relief. The incision was made in the median line, commencing at the lower edge of the hyoid bone and extending an inch below the cricoid cartilage. Immediately on its division, the trachea was fitted with a syphon-shaped leaden tube. This answered the double purpose of preventing the escape of blood into the trachea, and of allowing respiration to be carried on at a distance from the field of operation. The edge of the trachea was fixed to the skin by two long wire sutures passed deeply into the tissues. No other sutures or dressings were used. The leaden tube was left in for the first twelve hours, afterwards tubes of gutta percha, and finally of vulcanite were used. These tubes filled completely the trachea and effectually prevented the entrance of anything but air. The wound was not irrigated on account of the gulping and irritation which would be set up, but all the discharges were carefully sucked up by a wide-mouthed glass syringe. The air around the bed was kept heavily carbolyzed by means of a small current of steam from a kettle containing carbolic acid solution. On October 8, twenty-eight days after the operation, the wound had contracted to the size at which it is desirable to keep it, and a Gussenbauer's voice-apparatus is being moulded to fit it.—*The Lancet*, Oct. 13, 1877.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, December 22, 1877.

## WHY THE PROFESSION IS CROWDED.

We have before us a pamphlet containing the address delivered by Professor Pepper, M.D. at the opening of the 112th course of lectures in the Medical Department of the University of Pennsylvania, together with statistics of medical schools and doctors abroad, now published for the first time. In our issue of October 6th we devoted some space to a consideration of the subject-matter of the address. We would to-day like to call the attention of the profession to the very valuable tables which Dr. Pepper has drawn up to illustrate the status and number of medical schools in foreign countries, together with the proportion which has been found to exist in those countries between the whole number of physicians and the total population.

With a total population of 44,874,814 in the United States, there are 62,383 doctors, and 94 medical schools; one doctor to every 600 of the population. In France the population is 36,100,000; the number of physicians, 19,902; and the number of medical schools, 6; one doctor to every 1,814 persons. In Great Britain the population is 32,412,010; the number of physicians, 19,385; and of medical schools, 19; one physician to every 1,672 persons. In the German Empire there are 12,686 doctors and 23 medical schools to a population of 41,060,695; one doctor to every 3,000 units of population. In the Austro-Hungarian Empire there are 14,361 doctors, and only 6 medical schools, with a population of 35,904,435; one doctor to every 2,500 persons. These figures, which are evidently the result of a very thorough and careful study of the medical statistics of different countries, are highly significant. They show us that for equal units of population the United States has four times as many doctors and fifteen times as many medical schools as the Austro-Hungarian Empire; three times as many doctors and fourteen times as many medical schools as France; five times as many doctors and

four times as many medical schools as the German Empire; three times as many doctors and four times as many medical schools as Great Britain. We are further shown that the yearly number of medical graduates is 3,000 in the United States, 550 in the Austro-Hungarian Empire, 750 in France, 550 in the German Empire, and 1,743 in Great Britain.

If anything can prove beyond disputation the ruinous course which certain medical matters are taking in this country, it is the facts to which we have called attention. We believe that the principles which limit the supply to the demand, in all questions of commerce and trade, have an equal application—at least should have an equal application—in medical matters. It requires from 2,500 to 3,000 persons to support one doctor, therefore one doctor is enough in a community of 2,500 persons; if there are any more doctors, they will render the profession of medicine, in that community at least, a ruinous one. It is all very well and very high-toned to say that a doctor should never be a mercenary individual—should carry on his practice entirely without thought of pecuniary profit. Practically and rationally considered, such insinuations as these are nothing at all but mere sentimentalisms. The fact that work of all kinds has a fixed money value—that the laborer is worth his hire, will hold just as long as there is any work of any kind to be done. We say that any attempt to have it generally understood that a doctor is a walking charitable institution is as false as it is unfair to the profession.

There is a great deal of complaint made nowadays at doctors' exorbitant charges. Why do doctors make such comparatively high charges? Simply because there is so much competition in the ranks of the profession, that a physician of reputation is forced to demand a considerable fee as a simple matter of support. He feels that he has a right to live respectably, and he naturally takes a fair advantage of his opportunities. With one doctor to every 600 units of population in this country, how is a physician to keep body and soul together unless he charges reasonably well for his work. With the vast majority of doctors in large cities, it is about all they can do to pay for their ordinary living expenses. The world at large expects too much from the doctors. They are only men, and, like other men, altogether dependent upon their own exertions. There are too many doctors in other countries—what then shall be said about this country? And yet the 94 medical schools still go on turning out their annual quota of graduates, the vast majority of whom, finding medicine not what they expected to find it, fall by the wayside and take up some other profession. A whole book might be written upon the innumerable vicious results of the over-production of medical men; but we will not tire our readers.

There are also in the Doctor's pamphlet some interesting statistics of the requirements for the degree of

M.D. abroad. In Germany the medical schools are supported by the government. The matriculate must either show the certificate of a gymnasium, or pass a preliminary examination. The course extends over four terms of nine and a half months each. The right to practise medicine can only be obtained by passing the State examination before an impartial board appointed yearly by the ministry. This examination is more severe than that passed by medical candidates for the army and navy in this country. In the year 1875, in Germany, only 292 out of 378 applicants for the license were passed. In the Austro-Hungarian Empire the schools are also supported by the government, and the matriculate must show a certificate, or pass a preliminary examination. The course of study extends over a period of at least five years of about nine months each. In France there are what are known as preparatory schools, which give the degree of health officer (*officier de santé*). The possessor of this degree can only perform minor surgical operations, and cannot practise out of the department of France in which the degree is given. To matriculate at these schools, the candidate must show a thorough knowledge of the elements of learning. The course extends over five years. In addition to the above there are the academies. To matriculate at an academy, the applicant must have the degrees of bachelor of arts and sciences. The course extends over four years of ten months each. In Great Britain the matriculate must show a degree in arts, or pass a preliminary examination. The course extends over four years of nine months each.

Dr. Pepper has also collected statistics for Belgium, Brazil, Canada, Chili, Cuba, Italy, Norway, Sweden, Spain, Venezuela, Russia, Denmark, Holland, and Portugal; but we have contented ourselves with a mention of the statistics of our own land and of four other prominent nations.

All these things are so plain, that he who runs may read. Everything which can offer advice, or give an example, points in one fixed direction. To this end the reduction of the quantity, and the improvement of the quality of legislation must be made. State examinations must be enforced, and the sooner the better. It is the only way in which order can be restored, the number of physicians reduced, and the diplomas of the majority of the medical schools rendered worth something more than the parchment they are written on.

#### MEDICAL CERTIFICATES IN THE DAILY PAPERS.

The Committee on Ethics of the Medical Society of the County of New York made its first report on Monday evening last. Although this was merely of a preliminary character, there is enough of it to show that the members of the committee appreciate the responsibilities resting upon them, and that they are de-

termined to do their duty. A proper initiative was taken in rebuking the writing of medical certificates in the daily papers, and in suggesting the only reasonable and suitable remedy for the growing evil, which is to the effect that "the offending parties shall at once withdraw their signatures from these advertisements, and thus place themselves in honorable record with this Society and the profession." This is the only course open to these gentlemen, one which we suggested some time since, and one which should have been taken by them of their own accord long ago, and when the certificates first appeared. As the case now stands, what would have been a matter of choice and ordinary prudence may become one of compulsion, which proceeding will carry a conviction upon its face. But the report is referred by rule to the Comitia Minora, which will doubtless take action at once, unless such may be made unnecessary by the prompt withdrawal of the names in question.

#### THE COLOR-LINE IN MEDICINE.

A recent number of the *Lyon Medical* contains some rather sharp remarks, *propos* of the action of the College of Physicians and Surgeons in this city in refusing admission to Mr. Barbosa on account of his color. The writer has evidently a hearty dislike for America, which he calls the classic land of humbug and of liberty; and for Americans, whom he politely designates as Yankees. It is true, however, that the action of the Faculty affords good grounds for sharp criticism, and it is not surprising that foreigners should choose to regard it as an example of the real value of the much-vaunted liberality of Americans.

#### Reviews and Notices of Books.

TRANSACTIONS OF THE INTERNATIONAL MEDICAL CONGRESS OF PHILADELPHIA, 1876. Edited for the Congress by JOHN ASHHURST, Jr., A.M., M.D., Fellow of the College of Physicians of Philadelphia, Prof. Clin. Surgery Univ. Penn., Surgeon to Episcopal Hospital, etc., etc. Philadelphia, 1877.

The success of the International Medical Congress of Philadelphia is a matter of history. As a meeting of medical men from every part of the globe, it was thoroughly cosmopolitan and strictly representative; as an organization for the transaction of business it was almost perfect; as a purely scientific convention, it was a model of its kind in the elaborate and varied programme of its papers and in the systematic discussion of the subjects. The volume before us is a full record of these transactions, and its value can be bespoken in advance. Not more fortunate than in the meeting itself was the committee in the selection of one of the first scholars of the country as the editor. It is unnecessary to say that Dr. Ashhurst has done his work well, and that as a volume the Transactions will meet the expectations of the most fastidious critic. But so much in a general way for the work before us. The volume contains all the addresses

delivered before the Congress, and, with few unimportant exceptions, all the papers read in the meeting of the several sections, and by them referred for publication. Considering the great pains which the Centennial Medical Commission took in selecting subjects and authors, it is not surprising that, unlike most volumes of its sort, it is filled with communications of first-class merit. There were eleven addresses in all: On Medicine, by Dr. A. Flint, N. Y.; Hygiene, by Dr. Bowditch, Boston; Toxicology, by Dr. T. G. Wormley; Surgery, by Dr. Paul F. Eve, Nashville; Biography, by Dr. J. M. Toner, Washington; Obstetrics, by Dr. Theophilus Parvin, Indianapolis; Medical Jurisprudence, by Stanford E. Chaille, of N. O.; Mental Hygiene, by Dr. John P. Gray, Utica, N. Y.; Medical Literature, by Dr. L. P. Yandell, Ky.; Medical Education, by Dr. N. S. Davis, Chicago; and on Medical Staff of U. S. Army, by Dr. J. J. Woodward, Washington, D. C. Included in this list is the history of the Medical Centennial Commission, by Dr. J. C. Hutchinson, Philadelphia, and the address of Dr. S. D. Gross, also of Philadelphia. There are also the reports of the sections, nine in number, as follows: On Medicine, Biology, Surgery, Dermatology, Obstetrics, Ophthalmology, Otolaryngology, Sanitary Science, and Mental Diseases. It is impossible to give even the titles of the different papers read, much less a synopsis of them; suffice it to say that each of the authors—who, by the way, were selected with care beforehand—wrote upon the subject with which he was considered to be best acquainted. The object from the first being to have American physicians and surgeons show their best work, it is not surprising that the volume before us is a more than ordinarily interesting and useful one of its sort. With volumes of transactions of other societies it is only to be compared in name, while, in fact, it so far leads all others as to seem entirely distinct of its class.

**WALSH'S PHYSICIAN'S COMBINED CALL-BOOK AND TABLET.** Third edition by RALPH WALSH, M.D., 326 C Street, Washington, D. C.

**WALSH'S PHYSICIAN'S HANDY LEDGER.** A companion to above. Same publisher.

WALSH'S Call-Book has some advantages not possessed by others, in that it can be commenced and ended at any time of the year, is of convenient pocket size, and has a very simple arrangement.

Walsh's Ledger, which is intended as a companion to the above, is a neat, handy, and convenient-sized blank book for the transfer of accounts. Each page represents a year's attendance. The names of the months are in a vertical line, while the days of the month are arranged horizontally across the page. The amount for each month can be footed up at the end of each line, and the whole footed up for the year at the bottom of the page. There is also a general letter index to the volume. Its arrangement insures simplicity and accuracy with the least possible expenditure of time and labor.

**PHYSICIAN'S POCKET CASE-RECORD AND PRESCRIPTION BLANK BOOK, WITH VISITING LIST.** Cincinnati: Robert Clark & Co. 1877.

MESSRS. CLARK & Co. publish two lists with the above title: one of pocket size to be carried around, the other of larger dimensions, to which the cases from the smaller book can be transferred. The arrangement is such as to enable the physician to take the points in the case together with the prescription written, and at the same time furnish a duplicate to the apothecary. There is also a suitable table for a record of the work

of each month. The larger work is three times the size of the smaller, and consequently each page contains three of the others.

**THE PHYSICIANS' DAILY POCKET RECORD AND VISITING LIST.** Published at the office of the *Medical and Surgical Reporter*. Philadelphia, 1878.

This is a convenient little book, which will answer the purpose of most physicians. One advantage possessed by it is, that it is so arranged that the practitioner can begin to use it at any period of the year without loss of space. The book could, however, be made smaller without detriment to its usefulness. Forty-eight pages are devoted to lists of medicines, with their prices and doses, to tables of fees, of human weights, of the examination of the urine, etc. These could be greatly condensed, or better left out entirely. The death and cash records might also be left out with advantage, and the space devoted to the visiting list. The book is of pocket size, is printed on good paper, and is strongly bound. It possesses a self-closing clasp, and contains a perpetual almanac.

## Reports of Societies.

### NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, Nov. 14, 1877.*

DR. E. G. JANEWAY, PRESIDENT, IN THE CHAIR.

(Concluded from page 798.)

**MALPOSITION OF AORTA AND PULMONARY ARTERY—THROMBUS IN HEART AND CEREBRAL EMBOLISM—DEATH FROM INTESTINAL HEMORRHAGE.**

THE PRESIDENT presented a specimen of the above, with the following history:

The subject of this case was a male child born January 16, 1876. He was cyanotic from birth, and suffered considerably from attacks of shortness of breath on exertion. During the first year of his life he had an attack of catarrhal pneumonia, from which he recovered. Previous to his becoming paralyzed he was able to say a considerable number of words.

In March, 1877, he became suddenly unconscious and paralyzed on the right side of the body. This happened in the morning. After several days he regained consciousness, and was subsequently treated by faradization for the paralysis. Under the treatment the paralysis improved considerably; as usual in hemiplegia, the leg recovered faster than the arm. Slight contracturing was becoming manifest in the hand. It was only on rare occasions, and that when strongly excited, that he could say "papa" and "mamma," after the advent of the paralysis. He would, however, when wanting water, point to it and say "ta." It should be stated that sensibility on the hemiplegic side was considerably impaired. On the evening of November 5, 1877, when convalescing from an attack of measles, which he had in common with two other members of the family, he was suddenly seized with vomiting. This was attended with evidences of pain, and was large in quantity. He soon showed evidences of thirst, and drank and vomited considerable quantities of water. At the time of the first vomiting he had a natural movement from the bowels. About 5 A.M. of the next day he had a passage from the bowels consisting almost entirely of fluid and clotted blood. This was sufficient to soil two

diapers, night-dress, and to soak into the mattress. He died about 1 p.m. of the 6th of November, and after death about a pint of blood escaped from the mouth and bowels.

I am indebted to my friend Dr. Castle for this ante-mortem history and for these specimens, which he brought to me for examination, removed by him at an autopsy on one of his patients. The heart, in its present state, is  $2\frac{1}{4}$  inches long over the ventricles, and 2 inches broad. On looking at it in front, the aorta is seen coming off in the position usually occupied by the pulmonary artery. The largest part of the ventricles also is in front and on the right side. A dissection of the heart shows that the ventricle wall from which the aorta arises is 7 mm. ( $\frac{2}{5}$  inch) thick; that this auriculo-ventricular orifice is guarded by the tricuspid valve, and receives blood from the right auricle. There is no deficiency in the septum between the two ventricles—a condition which has obtained in certain cases of transposition of these arteries. The right auricle receives the two venae cavae and the coronary sinus in the usual position. The foramen ovale is patent, the opening measuring 6 mm. in the transverse and 1 cm. in the vertical direction. The Eustachian valve is fairly marked.

The left auricle receives the pulmonary veins and discharged its blood into the ventricle from which the pulmonary artery arose. This auriculo-ventricular orifice, as you will see, is guarded by the mitral valve. The ductus arteriosus is still patent for a small probe, though this requires a little pressure to make it pass. It does not seem probable that this opening, admitting a probe of  $1\frac{1}{2}$  mm., could have aided more than to a very slight extent the circulation of blood. Another circumstance worthy of note is the small size of the ventricle from which the pulmonary artery arises. Its walls are about 3 mm. thick, and its capacity is much less than that of its fellow. In the cavity of the ventricle from which the aorta arose, the columnae cornuae were well marked, and the depressions between them considerable. In one of these I found a small, white ante-mortem thrombus, round, and of the dimensions of a large pea. The aorta gives off its branches as usual.

The brain which I now show was taken from this child. It shows a greater destruction of cerebral matter than I have hitherto seen occur; and it is the more noticeable as the child was improving so far as the influence of the cerebral lesion was concerned. The left hemisphere has to a very great extent disappeared. We can still see some convolutions of the lower part of the middle lobe, a part of corpus callosum convolution just above the centre and posterior part of the corpus callosum in the longitudinal fissure and the inner two orbital convolutions of the anterior lobe.

The rest of the brain on this side is held together by the pia mater, and is partly pulpy in the central portions, and at the periphery is indurated, showing in some places little yellow pigmented portions. With the exception of the portions mentioned above, this hemisphere must have been functionally useless. A section shows that the corpus striatum is destroyed, but that the optic thalamus is preserved.

Looking at the base, descending atrophy is noticeable in the left crus, in the left side of the pons varolii, and in the left anterior pyramid of the medulla oblongata. This latter was, previous to my placing it in the bichromate solution for hardening, of a grayish color, and can now be seen to be on the surface almost one-half smaller than its fellow.

I find that the middle cerebral artery of the left

side is obstructed just beyond its commencement, and is there smaller by one-half than its fellow. It feels like a cord. The anterior cerebral artery is preserved to the anterior communicating, and then becomes very reduced in size, and a small branch can be seen passing from the right anterior cerebral to the convolutions of orbital portion of frontal lobe which were preserved; also, in the longitudinal fissure at the point of preserved convolution of corpus callosum, a branch passed from right anterior cerebral to the left, and this latter artery is seen increased in size. The first portion of the posterior cerebral is of considerable size, and a branch passes to the preserved temporo-sphenoidal lobe convolutions. Further on the convexity of posterior lobe, this artery showed one of its branches obstructed. Whether this was due to embolism or thrombus from disturbed circulation, it is at this late date difficult to say. It seems to me that the extensive destruction effected by an embolism of the middle cerebral artery, in this case, is to be referred to the peculiar conditions obtaining in this child's circulatory organs; so that, when this artery was obstructed, it weakened the circulation of the posterior and anterior cerebral arteries to so great an extent that a proper anastomotic circulation was prevented, and the nutrition of parts supplied by these arteries was also impaired. It seems to me that the absence of any evidence of infarction elsewhere (spleen, kidney), and the fact of finding the obstructed middle cerebral artery, will do away with the supposition of a number of capillary emboli.

Dr. Castle states that the other lesions present were some bloody fluid in the pleural and peritoneal cavities, and an intense congestion of the ileum, and a slighter congestion of the colon. He states that no embolus was noticed in the superior mesenteric artery. I examined a portion of the intestine brought me, but its arteries showed no emboli. The liver, kidneys, and spleen showed no lesion, and the spinal cord was not examined.

It seems that a congestion of the intestinal vessels brought about the fatal hemorrhage. The cause for this may perhaps have been due to some disturbance of the circulation resulting from the attack of measles.

If we include this in the category of cases in which the ductus arteriosus was nearly or completely closed, to which I think it rightly belongs, it is one of a series of rather rare cases. I think that five only have been reported, the life in the oldest being continued to two years and eight months. There is a point about the circulation worthy of attention, and that is that there must have been a double current through the foramen ovale, or else we are unable to understand how the blood became mixed. A current from the vena cava inferior into the left auricle must have been compensated for by a reverse current from the left auricle into the right; or else, during the auricular diastole, the blood passed from one of these cavities into the other, and during the auricular systole the reverse took place.

Dr. Castle states that the sight of the eye on the paralyzed side was considerably weakened, and that Dr. Bull, on one examination, found that the retinal veins were markedly dilated.

---

A MONSTER.—A very robust woman in the valley of Locana, Italy, recently gave birth to a child that has two heads, four arms, two hearts and four lungs (?), but only one trunk and two feet. Both mother and child were doing well when last heard from.

## Correspondence.

## DEATH FOLLOWING VACCINATION.

TO THE EDITOR OF THE MEDICAL RECORD.

Sir:—During twelve years' perusal of medical journals I do not remember to have read an account of death following vaccination. Dr. Martin, in 1872, reported 400,000 vaccinations, with no case of death. Dr. Foster has never heard of a case of death where bovine virus was used. All the text-books I have had access to, mention no case of death unless complicated by erysipelas. A medical friend has heard of three deaths, but is unaware of the cause; whether from syphilis, erysipelas, or septicæmia. A non-medical friend has stated to me that he knew of two deaths, but thinks they resulted from the use of syphilitic virus.

Information concerning cases with an unfavorable termination cannot come amiss to our profession; therefore I would occupy your columns to report the following:

M. A., female, aged three years; perfectly healthy; parents healthy; was vaccinated by me, March 16, 1877, from a quill of bovine virus; had not been humanized; quill came directly from a reliable vaccine producer—a gentleman I know to be endorsed by the health-officers of St. Louis and Cincinnati. Vaccination was performed by scraping off epidermis one-third inch square with scalpel; previous to using scalpel it was dipped in alcohol and burned. Heard nothing from case till April 2d, seventeen days after vaccination; was then told arm was tender, and action of virus had been retarded.

April 5th, child was brought to me from its home, seventeen miles distant; found the arm to be much swollen, swelling extending to its shoulder, but *very slightly* red; glands in axillæ scarcely swollen; skin and subcutaneous tissue not inflamed; swelling more an œdema than the result of an inflammation. Vaccine sore as it should be at ninth to twelfth day, but giving forth an offensive odor. Removed scab easily, and below it found surface purulent, unhealthy, gray, and insensible to touch. To the excavation I applied chromic acid, and covered with a charcoal poultice; to the swollen parts surrounding sore, applied tincture of iodine. Patient was peevish, and complained slightly of chilliness; temperature  $102^{\circ}$ , pulse 120; no perspiration, no delirium. Directed mild nervous and arterial sedatives; moved bowels with potass. bitart.

April 6th, temperature  $101^{\circ}$ , pulse 125; peevish; swelling increased; extended up the neck, on to chest, and down the arm. Little complaint of chilliness; no delirium, no perspiration; odor of ulcer less offensive. Little food taken; complains of nausea. Directed to continue above treatment, adding quinine in tonic doses, urging milk, beef-tea, etc. During the day and until evening the symptoms continued the same, the swelling constantly increasing, the arm at the axilla being twice the size of its fellow. All color was lost, the skin having a pearly white hue.

During the evening the bowels were moved quite naturally, when the child seemed less restless; slept a dreamy, feverish sleep for an hour, and, aside from the local symptoms, was considered by its mother to be better. At 11 P.M. she awoke, spoke rationally to her mother, then lay back and was dead. The immediate cause of death is unknown, as no post-mortem was made.

In connection with this case several questions of interest arise. Erysipelas, syphilis, impetigo contagiosa, etc., have been communicated by vaccine virus in well-known cases. There is reason to believe that a *crust*, containing as it does matters other than dried vaccine lymph, is open to the suspicion of causing unhealthy vaccine sores, but in this case the *quill* was used.

Neither of the parents could be suspected of syphilis, and as the scalpel was heated with burning alcohol, no distrust could be attached to that.

As the virus was bovine, we would exclude an erysipelatos contagium. Nor did the sore and surrounding parts present the appearance of œdematous erysipelas. No cases of erysipelas were occurring in this vicinity at the time.

Some members of the profession are of the opinion that vaccinia is more severe during an epidemic of any cutaneous disease. If the belief has any foundation, it is proper to state that a mild epidemic of scarlatina was prevailing at the time, and fully one-fourth of all cases vaccinated by me had symptoms of uncommon severity; many of the cases of vaccinia having deep ulcers discharging much pus, some characterized by a markedly offensive odor, one patient having well-marked symptoms of septicæmia, which in a severer form and occurring in an infant I believe to have been the cause of death in the case narrated above.

In the non-professional world such cases produce a dread that would annihilate vaccination, though a million of lives by it were saved where indirectly one by it is lost; it being impossible for such to believe that pyæmia following the vaccinator's scalpel is the same as that consequent upon a gunshot wound.

JESSE HAWES, M.D.

GREELEY, COLORADO.

## TÆNIA TREATED WITH CARBOLIC ACID.

TO THE EDITOR OF THE MEDICAL RECORD.

In vol. IX., p. 156, is a report of a case of tænia, treated by Dr. S. A. Brown, U.S.N., with carbolic acid. I have now a little additional experience in the use of this new agent, which I think preferable to anything in the routine treatment generally adopted. I transcribe from my case-book as follows:

Ralph D., æt. 4, good parentage, and ordinarily healthy; rather thin in habit, and of a nervous temperament. First discovered October 6, 1877, in stools. As the child had eaten freely of grapes, ordered its continuation, and prescribed santaline gr. vi., to be taken in two powders one hour apart at bed-time, followed with castor-oil in morning. This was pursued for three consecutive nights, with an abundant exfoliation of tænia joints. As it was greatly debilitating, I discontinued for a week, with the grape diet to be kept up, the exfoliation continuing. It was again repeated, with same results. Not being satisfied, I gave, October 23d:

℞. Acid carbolic cryst. . . . . gtt. iv.

Glycyrrh. pulv. . . . . q. s.

℞. Ft. pil. No. ix.

Sig.—Five to be taken the first day, four the second, followed each time by castor-oil. Diet to be restricted to chicken broth, etc., etc. Obtained some five feet more.

The exfoliation continuing, I gave Nov. 12th the same prescription, with carbolic acid increased to gtt.

vi. Four pills were taken, and we obtained about three feet additional. November 20th, three pills were taken, and we obtained eight and one-half feet, including head. The entire parasite measured about thirty feet. There was no disturbance of digestion, and not a single unfavorable symptom.

J. W. BROWN, M.D.

MOTTVILLE, N. Y.

## QUININE AND URTICARIA.

TO THE EDITOR OF THE MEDICAL RECORD.

MY DEAR SIR:—In a late number of your journal I see that Dr. Charles E. Slocum, of Defiance, Ohio, reports three cases, "all ladies, with whom the sulphate of quinine produced peculiarly unpleasant effects," viz.: "an eruption very severe and distressing in its effects," and the symptoms and effects of which were "mainly identical with those of *urticaria ab ingestis*." He reports these three cases as "unusual," and attributes the eruption solely to the use of the alkaloid of cinchona. In this section of Virginia—Tide-water Virginia—such cases are not at all unusual; have certainly not been unusual in my practice for the last twenty years; and for a long time, misled by the statements and opinions of the patients themselves, I attributed this urticaria myself to the quinine administered. I remarked, however, after treating quite a number of cases, that this urticaria not only always appeared in malarious districts, but generally in old intermittent fever patients, and that it observed a periodicity corresponding with the variety of intermittent to which the patient had been most subject—quotidian, tertian, or quartan—and that it supplemented the paroxysm, recurring, in other words, on the day and at the hour when the patient ordinarily had his chill. I at once concluded that the quinine, instead of being the cause, should be the cure of the malady; that the fault, after all, lay, as usual, with the *ingesta*, and that after clearing up the primal vice, and preparing the way for the proper absorption of the quinine, I should find the bane an antidote. I invariably, thereafter, commenced the treatment with a moderate dose of calomel, bicarb. soda, and Dover's powder—the latter being almost always rendered necessary by the state of general discomfort and irritation in which I found the patient; and after a gentle catharsis, gave quinine in appropriate doses, and at such intervals as the expected return of the paroxysm required. If there were much irritability of stomach, I added a little opium and creosote to the quinine pills, and have yet to see the patient who discovered that he was taking the much-dreaded alkaloid, however much he proclaimed the idiosyncrasy which prevented his taking it.

JOHN HERBERT CLAIBORNE.

PETERSBURG, VA., Nov. 30, 1877.

## ANOMALOUS CASE OF OPIUM-POISONING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Seeing in your edition of November 10th an article on "An Anomalous Case of Opium-Poisoning," I am induced to record a peculiar case that occurred in my practice some years ago.

J. P., at. 29, single, blacksmith, in strong and robust health, a moderate drinker, rarely if ever becoming intoxicated, presented himself at my office one morning about half-past eight, in the summer of 1873,

very much excited, and asked me to give him some poison which would insure a sudden and immediate death. While reasoning with him on the error of his ways, he exhibited a powder containing about one grain of morphine, part of which he spilled while showing it. Before he left (about nine o'clock) he quieted down and promised to behave himself, but refused to give up the morphine. I then started on my round of morning calls, returning to my office a few minutes before twelve, when I found a messenger there, who told me J. P. had taken poison. Taking my electro-magnetic battery with me, I was with him in a few minutes. I found him in bed with his clothes on, perfectly himself, and not in the least excited. He told me he had taken the powder exhibited at my office about an hour and a half before (corroborated by others), and that, as he was determined to die, it was useless attempting to save him. There was absolutely no symptom of poisoning of any kind, nor any effect of an opiate, except possibly the lack of excitement, although, as above stated, he was quiet before leaving my office. I made him get up, which he did with ease. Considering it my duty to guard against possible dangers, I produced free emesis (with mustard and water) without the least difficulty or delay. His stomach was loaded with undigested food. After the emesis he drank several cups of strong coffee, then laid down and was quiet, without any tendency to somnolency. I had sent to the druggist from whom he said he had bought the powder, to find out the quantity he obtained. The answer returned was, "One grain of morphine." My fears were now allayed. However, I remained with him until three P.M., when I shook hands with him preparatory to leaving. He was cheerful and chatty. I then went across the room, spoke a few words to the family, and was going out, when I heard him breathing stertorously. I went to him, but could not arouse him. His pupils had suddenly contracted to pin holes; his breathing was greatly reduced in frequency, and was labored; he swallowed with the greatest difficulty. I immediately applied the battery, gave a hypodermic injection of atropine and enemata of whiskey, followed by efforts at artificial respiration. He died in eighteen minutes from the time he told me good-bye.

At the inquest it was discovered he purchased two morphine powders the day before, one containing five grams, the other one gram. He certainly took all he swallowed before I saw him, as we sat by and watched him closely.

It was then about an hour and a half from the time he took the morphine until the emesis; four hours and a half from the time he took it until the first evidence of the drug, after which he lived eighteen minutes.

J. KINKEAD, M.D.

229 WEST 52D ST.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from December 9 to December 15, 1877.*

SMITH, J. R., Major and Surgeon. Granted leave of absence for fifteen days. S. O. 16, Department of the East, December 11, 1877.

WOLVERTON, W. E., Major and Surgeon. To accompany four companies of 1st Cavalry, detailed for field duty. S. O. 169, Department of Dakota, December 5, 1877.

KIMBALL, J. P., Captain and Assistant Surgeon. Relieved from duty in the Department of the East, and assigned to duty at Fort Columbus, N. Y. Harbor, S. O. 250, A. G. O., December 10, 1877.

FINLEY, J. A., 1st Lieutenant and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for two months' extension. S. O. 221, Department of the Missouri, December 6, 1877.

BARNETT, R., 1st Lieutenant and Assistant Surgeon. Leave of absence extended one month. S. O. 275, Division of the Atlantic, December 11, 1877.

NEWLANDS, W. L., 1st Lieutenant and Assistant Surgeon. Relieved from duty at San Diego, Cal., and to report in person at these headquarters for assignment. S. O. 153, Division of the Pacific and Department of California, December 3, 1877.

SHUFFELDT, R. W., 1st Lieutenant and Assistant Surgeon. Assigned to duty at Omaha Barracks, Neb. S. O. 141, Department of the Platte, December 10, 1877.

## Medical Items and News.

CONTAGIOUS DISEASES.—Comparative statement of cases of Contagious Disease reported to the Sanitary Bureau, Health Department, for the two weeks ending December 15, 1877.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-Spinal Meningitis.	Measles.	Diphtheria.	Small-pox.
Dec. 8.....	0	10	57	2	33	55	0
" 15.....	0	11	56	4	23	66	0

ART IN HOSPITALS.—Dr. Geo. Bayles, of this city, in a letter to the RECORD, advocates the adoption of transparent pictures painted on glass, for hospitals, as being least of all liable to collect dust. In order to guard against any possible roughness from paint, he advises the application of transparent enamel. The latter can be done at slight expense. These pictures can be then thoroughly washed and are practically indestructible.

DEATH FROM SWALLOWING A NEEDLE.—A death from the above cause occurred recently in the Richmond District Asylum, England. The autopsy showed that death had resulted from hemorrhage, due to a puncture made in the aorta by a common sewing-needle which had been accidentally swallowed. The stomach contained a large clot, forming a complete cast of that organ. The needle was found partly in the aorta and partly in the œsophagus, and was quite rusty.

TILTED BED FOR PELVIC PAIN.—Dr. Heywood Smith, of London, has devised a means of relieving the dragging pains of pelvic tumors, by raising the foot of the bed upon blocks, six to seven inches high.

VACCINATION IN THE PUBLIC SCHOOLS.—The Board of Health has ordered that all the pupils of the public schools shall either be vaccinated, or show certificates of protection.

CHLOROFORM HALLUCINATION AND ALLEGED RAPE.—A surgeon was recently indicted at the Northamp-

ton Assizes (England) for rape, while having a tooth extracted. The offence charged was alleged by the prosecution to have been committed while the prosecutrix was so far under the effect of chloroform or chloric ether as to be speechless and motionless, but not unconscious. The defence set up was that the prosecutrix was under the influence of chloroform to such an extent as to have caused her to imagine that to have been done which she described. For the defence, Dr. B. W. Richardson was called, and stated from the evidence in the present case he should say that the patient had reached the second stage. The usual symptoms accompanying that stage were loss of consciousness and, in the case of women, development of any hysterical tendencies, any operation being impossible at this stage, the patient resisting and screaming if touched. It was at this period that the patient was subject to illusions. A person who was deprived of the power of motion by chloroform would, in his judgment, be deprived of the power of sight. He knew from his own personal experience that persons in the second stage were subject to delusions as to what had been done to them during the time. He gave an instance of a lady who, in the presence of himself, her father and mother, and a dentist's assistant, while under the influence of chloroform, brought a charge against the dentist who was operating upon her precisely similar to the one in the present case, and continued firm in the belief that the charge was well founded long after the influence of the chloroform had passed off, and probably still continued in that belief. The other medical witnesses who were called, and who expressed their concurrence in Dr. Richardson's evidence, were Mr. Mills, administrator of chloroform at St. Bartholomew's, Dr. Hawksley, Dr. Saundby, of Birmingham, and Mr. West, Senior Surgeon of Queen's College Hospital, Birmingham. It was stated that all the medical witnesses for the defence had come forward to give their evidence entire gratuitously. The jury rendered a verdict of *Not Guilty*.

*Moral*—Medical gentlemen should never administer anesthetics to a female unless in the presence of witnesses.

ILLNESS OF PROF. STOKES, OF DUBLIN.—This distinguished physician and author has been stricken with apoplexy and consequent hemiplegia.

HARMLESS (?) INSANE.—A lunatic in the public asylum at Cadillac (Gironde), who has shown no signs of dangerous insanity, made a murderous attack with a knife upon the chief physician. Fortunately, only an insignificant wound upon the cheek was the result. A similar case has recently transpired at an asylum at Schönberg, the lunatic discharging five barrels of a revolver at a physician. Fortunately he missed his mark, and a valuable life was spared.

CONTAGIOUS DISEASES IN FRENCH HOSPITALS.—It is the practice to admit to the children's wards of the French hospitals every form of contagious disease indiscriminately, so that not unfrequently cases of diphtheria, scarlet fever, measles, and whooping-cough, are indiscriminately mixed. The medical profession of France has long protested against this practice, and now an effort is being made to introduce isolation wards.

DEATH OF DR. HANDSELL GRIFFITHS, OF DUBLIN.—Dr. Griffiths died of enteric fever, at his home in Dublin, aged thirty-two years. His researches in therapeutics gave him even at an early age a widespread reputation in this country.

**HYDROPHOBIA.**—The northern districts of Cornwall, England, are infested with mad dogs; hundreds of sheep have been destroyed, and a vigilance committee has been formed in every neighborhood.

**STRANGERS IN THE CITY.**—Quite a large number of medical gentlemen from different parts of the country are in attendance here upon medical lectures and hospital clinics.

**HOMEOPATHY.**—The Medico-Ethical Society of London advocated the admission of homeopaths to our societies, and recommended that the question of consultation should be left to individual discretion and feeling.

**UNIVERSITY OF AMSTERDAM.**—The new university which has been established in Amsterdam, in accordance with a decree passed last year, was opened with great pomp and ceremony on the 15th of last October. The university takes the place of the Athenaeum, which has flourished in that city since the year 1632.

**A CENTENARIAN.**—A woman named Annis Daguon died recently in Bordeaux, at the extraordinary age of 116 years.

**AN EPIDEMIC OF FEBRIS RECURRENS IN POLAND.**—Since the month of July an epidemic of febris recurrens has raged in the town of Ostrowo, in Poland. A peculiar feature of the epidemic has been the apparently complete absence of contagionness, which in all previous epidemics has been described as being very intense. In none of the families of the better class has there been more than one case of the disease. The first attack lasts usually three days, and the subsequent period of apyrexia the same length of time. In one closely watched case the second attack lasted four days. The second attack has often been followed by three or four, so to speak, abortive attacks, which consisted in a sudden chill followed by fever lasting only two or three hours. When the fever breaks, a profuse perspiration takes place, and the temperature falls far below the normal. The spleen seems, as a rule, but slightly enlarged. The nerves are not affected. Severe muscular pains are not usually present. On the other hand, the attacks are often accompanied by bilious vomiting. It is a striking fact that the great majority of the persons affected have been women. A few of the cases that were complicated with icterus resembled the bilious typhoid of Griesinger, and some of them terminated fatally in the first or second attack. The hygienic conditions of the town are reported to be very unfavorable. Abdominal typhoid is endemic, and the water of a number of the wells contains ammonia. The epidemic seems to be now on the decline.

**THE MALADY OF THE SCYTHIANS.**—Under this title Dr. Marandon de Montyel describes a malady which is peculiar to certain tribes of the Caucasus. The persons affected are men, and the affection consists in a loss of the attributes of virility before the advent of old age. The beard falls out, the genital organs wither, amorous desires are no longer felt, the voice becomes weak, and the body loses the strength and energy that it formerly possessed. Finally, the persons affected flee the society of those whose pleasures and labors they had previously shared, don the female costume, as they have already assumed the feebleness of the sex, and seek to assimilate themselves in all respects to the women, whose occupations they now share. The author passes in review all the opinions that have been advanced, from the time of Herodotus down to that of Boyard and Lallemand, to account for the

etiology of this impotence of the Scythians. He agrees with the illustrious professor of Montpellier in attributing this singular metamorphosis to seminal emissions and onanism, the cause of which is to be found in the equestrian habits of the people.

**A NEW JOURNAL.**—A new medical journal, the *Nosographul Ospitalului*, has just been started in Năamtu, Roumania. It is edited by Drs. Ulle and Moscovish, the former of whom is the chief physician, and the latter the assistant, at the hospital of Năamtu. Both are graduates of Paris. Dr. Ulle has already distinguished himself by a paper on the intestinal lesions of phthisis.

**M. BOUVIER**, member of the *Académie de Médecine*, recently died from the effects of an accident that had been occasioned by defective sight. He lived only a few hours after meeting with the accident.

**FIRE AT THE HÔPITAL SAINT-ANTOINE.**—On the evening of November 15th a large fire broke out in the Hôpital Saint-Antoine, in Paris. The wooden pavilions situated on the Rue de Chaligny were entirely destroyed. Two paralytic women lost their lives in the fire.

**JULES ROUX**, inspecteur-général of the French navy, corresponding member of the *Académie de Médecine*, died in Toulon on November 16th at the age of seventy years. He was the author of several scientific works, and was a frequent contributor to the medical periodicals. In 1842 he was appointed to the chair of anatomy and physiology in the naval school of Toulon. His principal work was entitled *De l'ostéomyélite et des amputations secondaires*, and was founded on cases observed in the naval hospital at Toulon. He also published memoirs on superficial angiolenitis, on diphtheria of the respiratory passages, on trepanning of the mastoid process, on amputations, resections, etc., etc. In 1847 he published in the *Mémoires de l'Académie de Médecine* an important paper on scapulo-humeral hydrarthrosis treated by iodized injections. This paper was the subject of a report by Velpeau, and gave rise to an important discussion. Jules Roux was one of the most distinguished surgeons of the French navy.

**TRICHINOSIS IN LEIPSIK.**—A mild epidemic of trichinosis broke out a short time ago in Leipsic. The disease, according to the official statement, has been traced to Brunswick "mettwurst," a kind of pork sausage. The epidemic has attacked chiefly the upper classes, the families of several professors being affected. Among others, a young medical professor has been attacked, but fortunately his attack is a slight one. The authorities have been urged to seize the pretty large stock of the diseased sausage that is still on hand in the city, in order to prevent the further spread of the epidemic.

**THE MEDICAL JOURNAL ASSOCIATION OF THE CITY OF NEW YORK.**—At an annual meeting, held December 7, 1877, the following gentlemen were elected officers of the Association for the ensuing year: For President, Dr. Robert F. Weir; for First Vice-President, Dr. H. F. Walker; for Second Vice-President, Dr. W. T. Lusk; for Recording Secretary, Dr. P. B. Porter; for Assistant Recording Secretary, Dr. W. T. Bull; for Corresponding Secretary, Dr. A. McL. Hamilton; for Treasurer, Dr. W. F. Cushman; for Librarian, Dr. J. H. Emerson. For Directors: Drs. H. P. Farnham, W. Johnson, C. M. Allin, and B. Robinson.

A quorum not being present at the latter part of the meeting, a fifth director was not elected.

## Original Lectures.

### ABORTION: ITS SYMPTOMS AND TREATMENT.

BEING THE SUBSTANCE OF FOUR LECTURES DELIVERED BEFORE THE MEDICAL CLASS OF THE UNIVERSITY OF PENNSYLVANIA.

By R. A. F. PENROSE, M.D.

(Reported for THE MEDICAL RECORD.)

THE great accident of pregnancy is abortion. By abortion is meant the expulsion of the product of conception from the womb before the end of the seventh month. As there is no adhesion between the ovum and the uterus during the earlier months of pregnancy, abortion at this stage is very frequent.

As soon, however, as the chorion and decidua are developed, separation becomes more difficult, and a miscarriage is much less likely to happen. Thus, it may be said that the chances of abortion diminish as gestation advances. The older accoucheurs thought that these early abortions were very common, and if they occurred before the seventh day they were called *effluxions* or *shours*. Thus, Smellie says that at this time abortion is frequent, since "the embryo and secondaries are not yet developed, and the ovum is liquid and unformed." The reason really is, that at so early a date the ovum is very small, and so may easily escape and cause but little trouble. [We may even, with propriety, say that the escape of the ovum before the twentieth day would constitute an effluxion.]

Abortions, indeed, are much more frequent than any of you would suppose. According to statistics prepared by Dr. Whitehead, of the Manchester Hospital, in Manchester, England, among 2,000 pregnant women there were no less than 1,222 abortions; 37 out of every 100 women aborted at least once before reaching the age of 30. If to this number we add all the effluxions which took place, the grand total would be much larger. I think we may safely say that ninety per cent. of married women nowadays abort at some period of their lives. As it has been discovered that 106 boys are born at full term to every 100 girls, it would seem that abortion is more frequent in the case of females than in that of male children. Abortion may be of three kinds: *Spontaneous, accidental, and designed.*

#### CAUSES OF SPONTANEOUS ABORTION.

These may be divided into three classes, viz.:

- I. Those resulting from the constitutional peculiarities of the mother and father.
- II. Those resulting from the condition of the uterus and its appendages.
- III. Those resulting from a diseased condition of the ovum.

There is a profound sympathy between the uterus and the rest of the human organism. Any strong mental impression may bring on abortion.

Among *constitutional* causes may be mentioned plethora, anemia, the nervous temperament, and constitutional syphilis. [Syphilitic infection is usually of maternal origin. There is still a question as to whether the father can infect the child in the womb.] Where the father is exhausted by debauch or old age, the product is usually aborted. In an instance where a healthy young woman marries a debauched old man, she will probably abort after every conception; while,

if the old man dies, and she marry a young and vigorous husband, she will carry every conception to full term. It has been very properly said that "old men should never worship at the shrine of Venus." Syphilis is an extremely frequent cause of abortion. When a man once gets constitutional syphilis, there is not much hope of his ever having healthy children. For this reason I say that a man who has once had constitutional syphilis had better always remain a bachelor.

#### CONDITION OF THE UTERUS AND APPENDAGES.

Under this head may be placed all the conditions that interfere with the development of the ovum. Among these may be mentioned displacements, inflammatory affections of the uterus and lining membranes, tumors, degeneration of the uterine tissue, diseases of the ovaries, rectum, or bladder.

In this connection may be considered the class of cases which are known as *periodic abortions*. These are due to menstrual congestion of the mucous membrane, a diseased state of the womb, or some abnormal organic condition. Shultz mentions the case of a woman who aborted twenty-two times at the end of the third month. I have had under my own care within late years two patients, both suffering from retroversion and chronic endometritis, one of whom aborted five times at the end of the third month in three years, and the other six times in four years at the same period.

The most common causes of abortion are those which *reside in the ovum itself*. Velpeau tells us that, in 150 abortions which he examined, one-half of the embryos were diseased. We see in this fact the kind conservatism of nature, which destroys all her imperfect productions. According to the general statistics of births, one child out of every three dies before the end of the first year. So, in the first year of infant life, nature proves her works, and, like Saturn, devours all her children until a Jupiter is born. Every infant's death, therefore, should not be a cause of mourning.

Almost all the diseases which occur after birth may be present in uterine life: inflammations of mucous membranes, dropsies of serous cavities, diseases of the liver and kidneys, tuberculosis, diseases of the cord, such as stranglings, twistings, knots, etc. Small-pox may be developed in the fetus while the mother shows no symptom of the disease. Thus, Mauriceau, the celebrated French gynecologist, states that, although his mother showed no sign of the disease, his twin brother was born dead from small-pox, and he himself delivered the day afterwards with pox on his body. The great majority of intra-uterine diseases are the results of constitutional syphilis in the parents. In addition to the above disorder, there may be numerous diseases of the placenta and membranes—hydatid disease of the villi, alteration of the amnion, ossification or fatty degeneration of the placenta itself. Dr. Barnes has devoted much time to a study of fatty degeneration of the placenta. He states that it is caused by syphilitic infection resulting in an imperfect formative force in the ovum. Its symptoms are very obscure.

It does not matter in what way the doom has gone forth, the product must die. In such instances, abortion is a most fortunate occurrence.

#### CAUSES OF ACCIDENTAL ABORTION.

Accidental abortion is more likely to occur at a menstrual period than at other times. Its causes are numerous. Any profound physical or psychological impression may produce a miscarriage—such as a violent fall, a sudden fright, great grief. So, too, abortion is

frequently produced by irritation of a distant organ; a nipple, for example. In fact, any severe disease of the kidneys, stomach, rectum, ovaries, or vagina may bring on sudden abortion. On one occasion it was brought on by a speculum examination. The application of strong nitric acid, or nitrate of silver, will often cause abortion. A very common cause is coition, which must be carefully abstained from in all cases of irritation of the uterus, such as rheumatism and congestion. Coition is mentioned by older writers as a very frequent cause of abortion. When the danger of abortion is imminent, coition should of course be avoided. But shall coition be advised, or forbidden in healthy pregnancy? The best answer that can be given will be to relate the personal experience of some men who ought to know. Mauriceau said that coition must be avoided during the course of pregnancy. Mauriceau lived forty-six years in married life, and never had a child. Dionus said that caresses during pregnancy did no harm. Dionus's wife was pregnant twenty times, and gave birth to *twenty children at full term*. Aristotle gave it as his opinion that coition renders labor easier.

Another very frequent cause of accidental abortion is the careless use of the uterine sound. I might give you a number of cases which have happened in my own practice, where, had I believed the history of the case brought by the patient, and used the sound without further precaution, I might frequently have produced a miscarriage. Therefore, I advise you never to introduce the sound for the diagnosis of supposed uterine disease until you have eliminated the possibility of pregnancy.

Among other occasional causes are small-pox, scarlatina, typhus fever, and pneumonia; also certain oxytocics, such as ergot, borax, savin, cannabis indica, gossipii radix, and galvanism. In Brazil, the decoction of the green pineapple is used by the native women as an abortifacient. Psychological emotions are also potent causes. A good instance of this may be found in the narrative in the Book of Samuel, concerning Eli's daughter-in-law: "And his daughter-in-law, Phinehas' wife, was with child, near to be delivered; and when she heard the tidings that the ark of God was taken, and that her father-in-law and her husband were dead, she bowed herself and travailed; for her pains came upon her." Any powerful drug in an overdose may bring on abortion. [I shall omit the mention of designed abortion until I come to speak to you of the operation for the premature induction of labor.]

#### THE SYMPTOMS OF ABORTION.

The two main symptoms of abortion are pain and hemorrhage. The pains come and go, and are much the same as labor-pains. The hemorrhage may be more or less profuse, and is due to the separation between the ovum and its uterine connections. The symptoms depend largely upon the cause which occasions the abortion, and the period of pregnancy at which it occurs. The symptoms of an effluxion, or of abortion in the early months of pregnancy, are not at all severe. The woman may be entirely unconscious of the fact; the ovum be mistaken for a clot, and so escape notice. When abortion occurs in the later months, the symptoms more closely resemble those of natural labor. After the formation of the placenta, the signs and symptoms are exactly those of natural labor. The cervix dilates, the membranes rupture, and the fœtus is expelled. In the first and second months, if abortion occurs, the ovum is expelled entire. This is always a fortunate circumstance. The uterus is left

entirely empty and contracts rapidly. In the third and fourth months, however, the placenta is relatively large, and its connection with the uterus close. At this period the contractile powers of the uterus are unable to break up the utero-placental adhesions. Two conditions are always present in later months, to render abortion dangerous, viz., a large placenta and feeble uterine muscles. If abortion occurs at this time, the membranes rupture, the embryo is expelled, and the uterus, instead of being entirely empty and able to contract thoroughly, closes upon the placenta and membranes, and all symptoms subside. In the course of a variable period, these membranes are detached and expelled. This may not happen, however, for several days, and even not for several months. Abortion occurring at this period is, therefore, most dangerous. The retention of the placenta makes it impossible for the uterus to contract thoroughly, and there may be hemorrhage, or the placenta may putrefy and bring on general septicæmia. In cases of spontaneous abortion, we frequently meet with premonitory symptoms, but in accidental abortion the action is sudden, and we have no notice of the event until it is upon us.

When abortion comes on slowly the general symptoms are those of depression, nausea, lassitude, fever and ague, palpitation, etc. Should the embryo die in the womb, the symptoms of pregnancy will suddenly disappear. The weight in the hypogastric region will increase, while the abdomen diminishes in volume. The fetal movements are no longer felt; there is no longer any pulsation of the fetal heart. If the fœtus be dead, the intra-uterine temperature will be found to be one degree lower than during its life. After the death of the fœtus the mammary glands usually swell up, and in the course of forty-eight hours some milk may be squeezed out of the nipples.

After its death the fœtus is a foreign body in the womb, and is generally expelled in the course of a few days or weeks, but it may be retained for a much longer time. The prolonged retention of the fœtus need not of necessity cause any bad results, for, as the air is unable to gain access, the mass does not putrefy, but shrivels up and softens, and in the course of time is either absorbed or thrown off as a mole. In the case we have just been considering the membranes will not have ruptured; but, should the fœtus die and the membranes be ruptured, the symptoms would be different. Oxygen gains entrance to the womb and causes rapid putrefaction of the product of conception, as a result of which the mother's system may be fatally poisoned. In spontaneous abortion, where the expulsion of the child is gradual, there is much less danger from hemorrhage than where the labor is suddenly brought to an end by some accidental cause. In the first instance the contraction of the womb gradually obliterates the calibre of the utero-placental vessels, and so no blood can escape. When, on the other hand, miscarriage is brought on by violent or acute causes, gestation is brought to a sudden termination, pain sets in, and hemorrhage may be very great; the product is expelled very slowly, because the cervix is long and hard, and the contractile powers of the womb very feeble.

#### THE DIAGNOSIS OF ABORTION.

The diagnosis is very difficult in the earlier months. Abortion can only be made known at this period by the discovery of the ovum in the discharges; therefore you should direct that all the discharges be saved for your inspection. At a later period of pregnancy

we have the history of the case, the nature of the pains, and the presence of hemorrhage may be noted. We also can call to our assistance the signs furnished by a vaginal examination.

#### THE PROGNOSIS OF ABORTION.

Your prognosis will vary with the period of pregnancy at which the abortion occurs, and with the cause which produces it. Abortion is most dangerous during the third, fourth, and fifth months, because at these periods the placenta and membranes are usually retained. The prognosis is generally more favorable in spontaneous abortion than in accidental, for in accidental abortion the hemorrhage may be so rapid and profuse as to rapidly destroy the patient. So, in the majority of cases of criminal abortion, the victim dies from hemorrhage. When abortion is produced by small-pox, scarlatina, dysentery, or pneumonia, it is often exceedingly fatal to the mother. Dr. Wm. M. Welsh, resident physician at the Municipal Hospital for infectious diseases in this city, published some very interesting statistics in connection with the small-pox epidemic in this city in the years 1871-72. According to these figures, among forty cases of pregnant women taken with small-pox, twenty-seven recovered and thirteen died. Of these forty women twenty-four aborted; fifteen aborted early in the course of the disease, and nine during convalescence. Of the fifteen who aborted early, nine died and six recovered; while of the nine who aborted during convalescence, all recovered. We draw from this table the conclusion that abortion occurring in the early stages of small-pox is quite frequently fatal.

In cases of periodic abortion, the woman's general health is very likely to suffer, and a woman who has aborted once is more prone to do so again. After abortion has taken place the patient is more liable to chronic disorders, and less exposed to acute disorders, than she would be if confined at full term. Abortion may be said to be one of the most common causes of uterine disease.

#### THE TREATMENT OF ABORTION.

The treatment divides itself into two heads: the *preventive* and *curative* treatment. The preventive treatment is that by means of which we prevent the repetition of abortion. Here a knowledge of all the causes is indispensable. If plethora, anæmia, or nervous irritability exist, they should be modified or removed. If there is syphilis in either of the parents, they must undergo a prolonged anti-syphilitic and tonic treatment. This treatment must be steadily pursued for several years. Where the abortion is due to any local disorder, such as chronic endometritis, hypertrophy, prolapse, retroflexion, or erosion of the womb, the patient must be placed upon a steady course of treatment for the removal of these causes. Suppose, however, that we are called in to prevent the occurrence of a threatened abortion, what shall be done? If a syphilitic mother become pregnant, she must be subjected to a mercurial treatment and the local condition thus modified. If the ovum be already diseased, it will be impossible to prevent abortion. Indeed, under such circumstances, abortion would be a most fortunate circumstance, and on no condition should we attempt to balk nature in such a case.

The first question we should ask ourselves in all cases of threatened abortion, is: Why is it threatened? Upon the answer to this question depends all our treatment. If the ovum be diseased or dead, do not try to prevent the abortion. The family history

will enable you to determine whether the ovum be diseased; if the product be dead, you will have the signs of death in utero. Suppose, however, that the product is not dead and not diseased, shall the abortion be prevented? The next question you must ask is: Can I prevent it? The embryo may be so far expelled that it would be worse than useless to interfere. The answer to this question depends on the dilatation of the os and the amount of hemorrhage. If the hemorrhage has been large, and the amount of blood lost considerable, the probability is that the utero-placental connections are so separated that abortion must ensue. Should a vaginal examination show the os uteri to be well dilated, and the membranes bulging, matters have gone so far that you cannot hope to prevent abortion, and therefore should assist it. There are various remedies for the hemorrhage. A drachm of the fluid extract of ergot may be given every three or four hours. I prefer the old wine of ergot given in doses of two drachms every hour or so. In addition to the ergot, the books tell you to apply cold cloths, ice, and vinegar to the abdomen, and to give gallic and tannic acid, or acetate of lead internally. I don't believe in any of these remedies. They are not half direct enough for me. If ergot does not control the bleeding, the next best thing you can do will be to tampon the vagina. A tampon acts in two ways: (1) it plugs the vagina; and (2) it stimulates the uterus to increased efforts. Never, however, put in a tampon unless you have given up all hopes of preventing the abortion. If you don't happen to have sponge-tents, tear up any napkin or piece of cloth that comes to hand and plug up the vagina. Sometimes I have had most excellent results from tamponing the mouth of the uterus with a sponge-tent or laminaria.

Now, as regards the curative treatment. If abortion occur during the second or third month, strive to secure a complete evacuation of the uterus. Otherwise the placenta will remain behind, and, becoming detached in the course of a day or so, will give rise to very serious hemorrhage. If the abortion occur in the fourth, fifth, sixth or seventh months, the membranes may be ruptured without danger if the hemorrhage proves excessive. When the child has been expelled, introduce your finger into the cavity of the uterus, and feel for the afterbirth. If it still remains in the cavity, it must be removed at all hazards. Have the woman brought to the edge of the bed, place one hand upon the abdomen, and insert a finger of the other hand into the uterus. Press the uterus well down upon your finger inserted into it, and scrape away until you have removed all the afterbirth. Never leave this work to nature, but see to it yourself at once. Where the placenta and membranes cannot be removed by the finger, various instruments have been devised for seizing them and bringing them out. Hodge's modification of Everett's bullet forceps is an entire failure, for the simple reason that you can't hold on to any foreign body after you have seized it with this instrument. Dewees's hook is not open to this objection, but it is so sharp that it might do much injury. The only instrument that has proved efficient is this species of duck-bill forceps which I now show you. I defy anything to get away which has once been caught by this instrument. If the placenta and membranes have begun to putrefy when you remove them, wash out the cavity thoroughly with some antiseptic injection.

Suppose that there is a hope of preventing abortion, what must you do? Put the woman to bed and give her two grammes of opium by the rectum. Or else

you may use a rectal suppository containing one-half a grain of the extract of belladonna and one grain of the watery extract of opium. Opium may be given hypodermically where the case is an urgent one. The bromides, too, should be freely administered in doses of from twenty-five grains up to five drachms. When the symptoms are very acute, ether or chloroform may be inhaled. Occasionally, where the woman is plethoric, from six to eight ounces of blood should be taken from the groin by leeches, or from the arm by venesection. Dry cups or mustard plasters may also be applied to the sacrum.

When abortion has taken place, the symptoms will generally be removed. There will be, perhaps, a lochial discharge for a day or two. You must now employ the after-treatment for labor at term. Keep the woman in bed for two weeks or more. Regulate her bowels by mild saline laxatives: do not use enemas at this time. Be careful, also, not to feed the patient too highly. Do not allow any meat for the first week. Ergot should be given steadily to promote the proper subinvolution of the uterus. When the patient gets up, put her on a tonic treatment, and impress it upon her that she is still an invalid, and must take no violent exercise. At her next menstrual period the flow will probably be excessive. This should be treated by rest and saline laxatives. The vagina should be well cleansed with astringent solutions, and ergot, gallic acid, and cinnamon tea administered internally.

## Original Communications.

### REPORT ON THE PATHOLOGY AND THERAPEUTICS OF DISEASES OF THE EAR.

By SAMUEL SEXTON, M.D.,

NEW YORK.

THE literature of otology for the past year furnishes much that is of interest in the department of pathology and therapeutics. Dr. Dalby, aural surgeon to St. George's Hospital, has continued his contributions to aural surgery. In the *Lancet* of January 22, 1876, his third article treats of closure of the external auditory meatus. He thinks dilatation is only temporary in cases where the thickening occurs from the irritation of discharges. Where exostosis is the cause of closure, and repeated syringing will keep the canal clear of secretions, he recommends no further interference. But should the canal become completely obstructed, causing great deafness or serious trouble from retained secretions, an attempt should be made to remove the growth.

Two modes of operating are mentioned: First, by the constant current. In one case three needles were introduced into the growth and a current from six elements of Störner's battery was passed for three minutes. Two weeks later this was repeated, and three weeks afterwards the growth was so loose as to be readily extracted, and the patient made a good recovery. In all cases holes cannot be drilled, owing to the hardness of the growth, for the introduction of the needles. In one case facial paralysis followed the operation, owing probably to the inflammation excited in the middle ear.

A second method suggested is the use of the dentist's drill, but its application is not mentioned in any case. Dr. Arthur Mathewson, of Brooklyn, however,

reports a case operated upon May 21, 1876. The patient was placed under the influence of ether. The integument was removed from the exostosis by scraping with a dentist's scaler.

Elliott's suspension dental engine was then used to propel the burrs which had been ground down to square drills for the operation. The growth was perforated at several points near its centre by a drill one and a half mm. in diameter. Larger drills, two and a half and three mm. in diameter, were successively used to enlarge the perforations, run them together, and by lateral pressure ream out the meatus. The drills penetrated with ease, although the growth was very hard.

The movements of the instrument were readily controlled, it being held in the hand like a pen. The operation required thirty minutes, and owing to the bleeding the operator could not see what he was doing, but was obliged to rely upon the guidance of a probe.

The result of the operation, after some weeks of closure of the meatus by the swollen integument, was an almost complete restoration of the calibre of the meatus, and a return of hearing.

Dr. D. H. Goodwillie, of New York, a practising dentist, in December, 1872, soon after the dental engine first came out, constructed revolving knives to be used with the engine for the removal of necrosed bones of the mouth and nares. In these operations he has been very successful with the instrument.

He has recommended it to otologists for the removal of bony growths situated in the meatus. It can also be used for trephining the mastoid.

Dr. Goodwillie prefers White's engine, the power of which is carried to the instrument by a wire cable within a hollow case. It can be run in any position.

It should be borne in mind that these knives cut, and do not scrape like a burr. When contained in the sheath the knife can be made to cut by passing the instrument between the osseous body and the walls of the meatus; or if there is not room sufficient for this, it can be presented *against* the object and pushed forward as it cuts its way.

The knives can be made of different sizes. The number of revolutions per minute most suitable for operations is about 1,500. The engine is capable of making 2,500.

Dalby devotes his fifth article to fatal cases of diseases of the middle ear. He divides them into two classes: those occurring soon after acute inflammation of the tympanum, and those following a chronic purulent condition. The first are dismissed as unavoidable deaths. The second he notices at length. The details of cases are given where the fatal result was probably averted by timely treatment. Dizziness is mentioned as the most common symptom calling our attention to these serious cases.

Epileptiform fits are frequent, and the presence of polypoid growth is common.

That many cases with grave symptoms present are now successfully treated is an evidence of the progress of otology.

Dr. Dalby's sixth article is upon syphilitic affections of the ear. He states that, next to scarlet fever, inherited syphilis may be regarded as the most fruitful cause of deaf-mutism, as it occurs in children who are born with good hearing power.

The writer's experience for many years in the large charitable institutions in New York devoted to diseases of the ear, would not lead him to similar conclusions.

Dr. Dalby regards the disease as essentially a ner-

vous one, and the time at which the patient usually becomes deaf is in early childhood—after he begins to talk—or the period between this and puberty. The difficulties in making a diagnosis in these cases between nervous deafness and a faulty conducting apparatus are mentioned.

The seat of the lesion in the former is as yet undetermined. It may impair the functions of the auditory nerve in the labyrinth, or before its termination in that structure.

In affections of the ear from acquired syphilis he has observed that deafness is seldom total, and that both ears are usually affected at the same time. Only once has he seen a case of total deafness, and it recovered after six months' treatment directed to the constitutional disorder.

He gives our countryman, Dr. Roosa, credit for his researches upon this subject, and coincides with Dr. Roosa in the belief that the inability of the patient to hear high notes may locate the lesion in the cochlea. Their combined experience impresses one with the importance of a long sustained course of constitutional remedies.

Where the affection shows itself by an extension from the fauces through the Eustachian tubes to the tympanum, the symptoms are the same as in cases of ordinary catarrh.

Dr. J. Hughlings Jackson, in an address on nervous symptoms with ear disease, refers to them as follows: *First*, neuralgia. *Second*, Bell's paralysis. *Third*, scrofulous tumor of the brain. *Fourth*, cerebral or cerebellar abscess and meningitis. *Fifth*, pyæmia. *Sixth*, hemiplegia. *Seventh*, epilepsy or epileptiform seizures. *Eighth*, aural vertigo. Some of these cases can only be said to be associated with ear disease. Referring to cerebral abscess, he says in some cases of chronic ear disease he has found in the cerebrum or cerebellum a mass of tubercle, in the place, so to speak, of an abscess from ear disease. The symptoms of these cases seem to differ from those of cerebral abscess only in chronicity. They were not tubercular meningitis. The literature of the subject is ably presented.

Dr. W. R. Gower publishes a series of articles on the diagnosis of auditory vertigo. Ménière's vertigo, a morbid state of the organ of hearing, Dr. Gower states, has passed from the presence of special aural surgery into that of general medicine, for the reason that the symptom vertigo has usually little apparent connection with its actual cause. The gastric symptoms often mislead both the patient and his medical adviser. The evidence on which the pathology of the disease is based is, first, the frequent association of paroxysmal vertigo with defect or disturbance of the function of the internal ear or auditory nerve; secondly, on some scanty pathological facts, which point to the existence in these cases of a morbid state of the semicircular canals; and lastly, on the well-known experimental evidence of the connection between the function of the semicircular canals and the maintenance of the equilibrium of the body.

The question of the mechanism of the action and disturbance of the semicircular canals is not entered into.

Dr. Gower reports some cases of labyrinthine vertigo.

The most important point in the diagnosis of auditory from gastric vertigo is deafness. Another symptom is tinnitus; and the loss of the power of hearing a watch in contact with the skull is a most significant change. The point of next importance is the character of the vertigo. The sensation which results from a primary disturbance is usually vague, a confused

sense of defective equilibrium; that which results from a labyrinthine affection is definite, a sense of movement in a certain direction, subjective or referred to other objects. Dr. Gower is convinced that in a vast majority of cases in which vertigo is definite and uniform, and apparently excited by gastric disturbance, an auditory defect will be discovered on careful examination.

The diagnosis from cerebral disease, apoplexy, and epilepsy is given, and will be found of great interest.

As to prognosis, in many cases it is a very obstinate affection; but a considerable amount of relief may be afforded; in several cases immunity for long periods has been obtained. The bromides, quinine, salicylate of soda, etc., are recommended.

Dr. A. E. Cumberbatch reports two cases of paracentesis of the membrana tympani for the evacuation of accumulations of mucus following subacute catarrhal inflammation of the middle ear. The tympanum was washed out daily with a solution of carbonate of soda for a few days—the fluid being forced through the tympanum to the throat. The cases selected for the operation were similar to those recommended by Schwartze, who has recently proposed to revive the operation in cases of catarrhal inflammation of the tympanum where the mucus secreted neither escapes by the Eustachian tube nor bursts through the membrane, but remains within the tympanic cavity. Dr. C.'s cases resulted very satisfactorily, the hearing being much improved in both. He believes the operation to be safe.

Hinton, who practised this operation and reported several successful cases, relied mostly upon passing the injected fluid from the meatus through the tube, while Schwartze and others adopted almost exclusively the opposite plan of injecting the fluid from the Eustachian tube through the tympanum.

Although Hinton spoke favorably of this operation in his work on Aural Surgery, published in 1874, otologists seem to hesitate to adopt it as they did the operation of tenotomy of the tensor tympani for tinnitus aurium. Could the diagnosis of accumulations be always unmistakable, the operation would doubtless be tried more often than at present.

Dr. Urbantschitsch, in an article on the modification produced upon the sense of taste and the salivary secretions by purulent inflammation of the middle ear, relates his experiments made upon fifty patients.

In forty-six cases the author found the sense of taste anomalous. In four cases only of unilateral otitis, the taste was preserved intact on both sides. His tests were made with a variety of substances—sweets, acids, salt, and the like—applied to different parts of the mouth, tongue, and pharynx, in order to determine the normal taste. He regards the alteration of function as depending upon the compression or partial destruction of the chorda tympani or the tympanic plexus.

The augmented sensibility of taste, etc., depends upon an irritation of these nerves.

Dr. Dreyfus-Brissac reports an interesting case of thrombosis of the right lateral sinus, from an internal otitis. The patient was a female aged thirty-seven, suffering from a uterine tumor. The case resulted fatally on the sixth day after the aural symptoms manifested themselves.

Dr. Lévi, of Paris, publishes in the *Annales des maladies de l'oreille, du larynx*, etc., an article entitled *Étude historique et critique sur le cathétérisme de la trompe d'Eustache et les divers procédés en usage pour faire pénétrer de l'air comprimé dans l'oreille moyenne*. He gives the literature upon this subject

from the recommendation of Valsalva to utilize the Eustachian passages in the treatment of middle ear diseases down to the present time. Mention is made of Guyot, a village postmaster, the inventor of the first Eustachian catheter, 1724, and then follows in historical order an account of the modifications of Cleland, 1741; Boyer, 1818; Itard, 1821; Gairal, 1836; Kramer, 1836; Delau, 1838; Triquit, 1857; Bonnafont, 1860 to 1873; Giampietro, 1863; Gruber, 1870; Tillaux, 1875.

After describing the various instruments used by these authors, and their methods of using them, Dr. Lévi thoroughly describes the manner of douching the middle ear with air by means other than the catheter.

Dr. Robert S. Cooper recommends an ear speculum for the removal of foreign bodies. It is constructed with a spout-handle, and has a scoop-nozzle; the scoop end is passed between the foreign body and meatus, and is so constructed that the water passes over the end of the scoop from the ribbon-shaped opening of the bore, which is placed *above* and somewhat short of the semi-flattened scoop-like extremity. I have found that a small stream of water projected by a syringe with considerable force against the side of a foreign body, will pass by and *beyond* it more readily than any instrument can, and the return current will bring the object within easy reach of the entrance of the meatus.

Dr. James Patterson Cassells urges that those who breathe habitually through the mouth are more liable to deafness than those who breathe through the nose with the mouth closed. This is owing, he claims, to the fact that intra tympanic tension is necessary for the perfect function of the apparatus of hearing, and that open nostrils and nasal respiration are essential factors in the maintenance of this normal balance of tension between the intra- and extra-tympanic air-passages.

He relates some observations which tend to the conclusion that nostril breathing is natural, and that in childhood we should attempt to compel such breathing.

He refers to an interesting statement made by Catlin, a traveller among the American Indians, who visited 150 different tribes living in a savage state. Among this large number—two (2) millions (?)—he states there were found only three or four deaf mutes, and not a single individual who was either dull of hearing or deaf. (I have always supposed aural disease must be quite frequent among a class so much exposed to the inclemencies of our north-western climate, and accounts are quite frequent of the natives who, while smoking, force the smoke out of their ears.) He explains the fact (?) by stating that it is the custom of Indian mothers to train their children to breathe with the mouth closed.

Dr. Cassells has published an article on Ear Disease and Life Insurance, which is of practical importance, and a valuable contribution to that subject.

The Connection between Diseases of the Organ of Hearing and the Nervous Trigemini is the subject of a paper by Professor Moos, of Heidelberg. He divides these diseases into (1) those of purely cerebral disturbance of the acoustic and the fifth nerve, in which the sensory portion only of the fifth is affected; and (2) cases in which organic affection of the hearing organ is present, generally acute or chronic purulent inflammation of the middle ear, with disturbances of the trifacial, the latter having commenced when the hearing organ had become affected.

He relates some illustrative cases, together with the treatment resorted to.

A new means of diagnosing the anomalies of the

tympanic cavity is given by Professor Gruber, of Vienna. He observes that when a tuning-fork is vibrating close to the healthy ear, and Valsalva's method is used, the sound is decreased by the increased outward tension of the membrana tympani.

If the patient, when this experiment is made, fails to notice that the sound is decreased, the membrane has already a *plus* tension outwards; but if the patient hear better under the experiment, there is a *minus* tension.

The vibrating tuning-fork placed on the head during Valsalva's experiment will be heard better in the normal ear, but if there be *plus* tension, the sound will be unchanged. If there be *minus* tension, the sound will be decreased, the membrane transmitting sound better than when lax.

In the *Medico-Chirurgische Presse*, Prof. Gruber, referring to artificial membrana tympani, prefers usually the use of cotton-wool to Toyubee's elastic membrane, for the reason that it is more adaptable to the conditions of the natural membrane, a continuous chain for the conduction of sound being formed. He often uses this kind of artificial membrane for the application of medicaments in preference to dropping solutions in the ear.

The relations of ear disease to insanity are shown by the report of a case by Dr. Williams. The patient, an inmate of Bethlem Royal Hospital, was on admission noisy, violent, and sleepless. In a few days he became quiet and sullen. In a fortnight after admission he again became excited and violent, when a profuse purulent discharge from the left ear was noticed. He stated that he had had this for months past. Hearing seemed unaffected. Slowly a large puffy abscess formed over the left mastoid, extending up over the squamous portion of the temporal bone. On pressure, pus escaped into the meatus. This swelling increased for a month, but the patient was regarded as too dangerous to be examined. A month later, however, the abscess was opened under the ether-spray, and he became sane at once. No further discharge took place from the ear. A fortnight later, under chloroform, a free incision was made, but a careful exploration failed to detect any cause for the discharge. For some time the patient complained of severe frontal headache and general malaise, but the wound healed, and the patient improved in every way. After watching him six weeks, he was discharged well. The origin of the abscess was doubtful. It extended deep in between the mastoid and parotid glands, but no diseased bone was anywhere found.

Several cases have recently been observed at the Bethlem Royal Hospital in which mental symptoms have abated on the onset of acute maladies, especially when implicating cranial nerves.

Dr. Williams is unable to state whether there was propagated an inflammation of the brain or a mere conduction of disease along a cranial nerve.

Dr. Hanbury Smith, when superintendent of an asylum for lunatics, mentioned several cases in which aural disease was intimately connected with the mental disturbance, in some holding the relation of cause to effect. Twenty-six years ago, when Dr. Smith wrote, attention had scarcely been called to this subject, and he is among the first to suggest the importance of making a thorough examination of the organ of hearing in connection with the treatment of lunatics. As institutions were then conducted, Dr. Smith could have had but little time to study the department of Otology, but his observations, made so long ago, should have certainly been more productive of results in this much-neglected field.

Under the heading of Some Practical Remarks on Aural Affections, Dr. Jones, of Cork, is publishing a series of articles, profusely illustrated with drawings, of the instruments usually used by aurists.

Although but little new or original is advanced, the articles may serve to attract the attention of the general practitioner to a subject he should undoubtedly be more familiar with.

Dr. George P. Field read an article before the Hærvæian Society, London, on the graver aspects of otorrhea.

The animal parasites which are frequently found in the external auditory meatus of the lower animals are described by Trautmann. In deer, *Dermomyssus*, or Hühnerlaus, has been found, as recorded by Von Tröltzsch, causing inflammation with excessive secretion. Dr. Trautmann has found in the ears of sheep, dogs, and rabbits, the *Dermatodectus Caniculi*. He has seen them present in the external, middle, and internal ears, but he thinks they are not capable of boring through a healthy *membrana tympani*. He believes that, having found their way into the tympanic cavity, they are able to pass through the *membrana tympani secundaria*. Before their entrance into the labyrinth, the rabbit shows little or no sign of discomfort, but, on their gaining an entrance there, the head was held in an oblique position, and a loss of equilibrium was noticed in attempting to move. Shortly after this, symptoms of meningitis set in, and death soon followed.

Though these animal parasites have not been found in man, the Doctor advises that children ought not to be allowed to fondle rabbits, dogs, or sheep, lest the animals being affected by these parasites, the children might receive them.

Dr. Wagstaffe recommends a new dilating speculum auris, constructed on the model of the tracheotomy canula. The instrument is expanded by a series of levers acted upon by a large milled head, by which the dilatation is controlled. It has a large polished external orifice, and is capable of being highly illuminated.

Several otologists during the past year have again drawn attention to the education of deaf-mutes. The number seen in the institutions in New York devoted to treating diseases of the ear, should greatly increase the facilities for teaching this class at the public expense.

Deafness during pregnancy, Dr. Pierce, of Manchester, thinks, begins with that state. Dr. Lennox Brown regards such cases as common, and believes they are not catarrhal, but thickening of the mucous membrane. Sometimes they are nervous in character.

Dr. Alexander Morrison describes a modification of Seigel's otoscope. It is a miniature Brunton speculum with exhausting-tube attached. The advantage claimed is that, on account of the reflecting mirror in the speculum, the observer looks directly on the membrane through a lens placed parallel to the eye.

Those who have labored under the disadvantage of using Seigel's otoscope placed lens can appreciate the advantage of Dr. Morrison's suggestion.

In this connection it may be stated that Dr. Purves, of Gay's Hospital, frequently uses Seigel's otoscope for the purpose of drawing out the tympanic membrane. The most prominent advance, however, in the use of Seigel's otoscope as a means of elevating the drum-head, was made by Dr. Pinkney, who used the flute-key lever-syringe of stomach-pump as a means of suction. This was undoubtedly an important step as ordinary suction by the mouth is in many cases totally insufficient.

Iodized preparations are urged as applicable in the treatment of most diseases of the ear in childhood by Dr. Ladréit de Lacharrière. As an injection in purulent inflammation he recommends the following proportions: Aqua, 1000; tr. iod., 30; iod. pot., 4; to be used night and morning. He bases this suggestion upon the belief that scrofula is the most frequent cause of otorrhea in childhood.

In an article on aural polypi he recommends as a caustic chloride of zinc made into sticks by the addition of a little wheat-flour; a little morphia is also added to the mixture.

Hardy, in an article published in the *Paris Médicale*, discusses circumscribed meningitis and Ménière's disease. At a meeting of the Medical Society of London, in January last, Dr. E. Wookes read a paper on the sympathy of the ear and mouth.

The frequent inflammation of the ear and otalgia caused by the presence of a decayed tooth or sore on the tongue was explained by the fact that fibrillæ belonging to the vaso-motor system of nerves mingled with those of the cerebro-spinal system; the former set of fibrillæ being brought into reflex relationship with the *nervi vasorum* distributed on the arteries of the part reflexly affected by means of the sympathetic ganglia, in which two sets of fibres communicate. In this way it was shown that distinct channels of communication existed between the vessel nerves which regulate the supply of blood to the ear, and the otic ganglion, while branches of the fifth nerve connected the carious tooth, and ulcers on the tongue also communicate with this ganglion. Morbid impressions affecting the latter would influence the former, and thereby produce vascular distention of the drum-head and contiguous regions, producing a veritable hyperæmia of these parts, to the consequences of which pain and inflammation were referred. Dr. Wookes explained what may be a frequent cause of spasmodic croup; a communication existing between the *nervi vasorum* of the vessels of the larynx and the auriculo-pneumogastric nerve supplying the meatus. Cold draughts of air falling upon the ear would through sympathy be the cause of spasmodic croup.

Laryngitis may thus occur from the presence of a foreign body in the meatus.

Nothnagel collects valuable facts, in a late volume of *Ziemssen*, on thrombosis of the cerebral sinuses in connection with aural affections.

Huguenin, in the article on inflammations of the brain and its membranes, contributes also to the literature of otology. He recognizes the frequency of the transmissions of inflammation from the temporal bone to the regions treated of. He says abscesses of the brain, which are secondary to affections of the ear, appear to be slightly more numerous than those which arise from injury. The affected part may be caries of the bony portions of the external auditory canal, as well as caries of the walls of the tympanic cavity, of the walls of the labyrinth, and finally of the mastoid process. After giving the most frequent seat of abscesses, he explains how the affection of the ear may lead to suppuration of the brain. Some abscesses are directly continuous with perforations of carious bones, but perforation of the bone is not a *conditio sine qua non* for the existence of an abscess of the brain.

Many cases are on record where the surface of the bone was perfectly intact; where, indeed, the existence of caries could not be positively demonstrated. Those interested in the subject will find the whole article very instructive.

The literature of this subject has been recently written up most ably by Green, in a brochure recap-

duced from the reports of the Boston City Hospital, Dr. Green presents the subject in an unusually clear manner.

Dr. Roosa reports a case of meningitis resulting fatally in twenty-eight days from the appearance of aural symptoms. The affection began as an acute *otitis media catarrhalis* with impacted cerumen which the patient thought was a facial neuralgia. Dr. Roosa calls attention to the rapid advance of the disease.

The danger attending the introduction of fluids into the nasal passages by means of the nasal douche has continued to interest aural surgeons in this country and abroad.

The weight of evidence is undoubtedly against recommending the use of the ordinary nasal douche so called.

Dr. Buck goes further than this in regard to the use of fluids in these passages, and objects to the use of the atomizer.

Shaw relates eighteen cases where injury was done the middle ear by various means of flooding the nasal passages.

In sixteen cases the liquid was introduced by the nasal douche and syringe, in one by the Valsalvian method, and in one by snuffing into the nostrils.

Dr. Lennox Brown agrees with the majority of otologists upon this subject in a late publication in which the subject is referred to.

The writer hereof once was compelled to cease using a powder which was smartly blown into the nasopharyngeal vault. Its use produced an irritation of the middle ear. The powder used was in part composed of the persulphate of iron. The patient suffered from chronic nasopharyngeal catarrh and catarrh of the middle ear as well. A rhinoscopic examination showed a very free opening of the Eustachian tubes at their pharyngeal termination.

Paulson recommends the use of carbolic acid in otitis without disease of the bone or the presence of polypi. He uses the acid one part to ten of olive oil. He avoids the frequent use of the syringe, and applies the remedy upon a small portion of cotton-wool, leaving it *in situ* until the next day, when the process is repeated if necessary.

Blake reports a peculiar form of obstruction of the external auditory canal which is described as being more pasty in character than the ordinary cerumen plug, and intermingled with flakes of yellowish sodden epidermis; the pasty mass is invested with a thickened layer of epidermis clinging closely to the lining of the canal.

It is found that this mass will not yield to ordinary syringing with water, but is best removed by aid of probe and angular forceps. Blake found in some cases great assistance from a saturated solution of carbonate of potash applied to the centre of the mass, carried by means of cotton-wool rolled upon the end of a probe. The resulting saponaceous mass was easily removed by syringing.

Agnew, in an article on otitis and its relations to "taking cold," recommends that those subject to colds should learn to endure draughts: first, by diminishing the morbid sensibility of the body by graduated exposure and friction of the skin in a daily air- or sun-bath, followed by such local sponge-baths as may be attended by speedy reaction.

The temperature of the water first used must not be lower than 80 Fahr.

The first air-bath should only consist of a few brisk turns across the bed-chamber. After a little practice the exposure may be increased to twenty minutes, and the temperature of the water used in washing accom-

modated to that of the outer air. At least four times a week, the patient while taking the air-bath, and *before* using the water, should rub the entire surface of the body briskly with "hair mittens and strop."

The object to be kept in view is to gradually and systematically lessen the morbid sensibility of the body by *daily* exposing the *entire* skin surface to air, light, friction, and cleansing, in an atmosphere as nearly as possible at the prevailing temperature.

This brief mention gives only the most suggestive portion of an article which is characterized throughout by the author's peculiarly forcible manner.

The Otological Section of the International Medical Congress of 1876, met in Philadelphia, Sept. 4th of that year. Dr. Buck, of New York, Dr. Burnett, of Philadelphia, Dr. Blake, of Boston, Dr. Spencer, of St. Louis, and others read papers. The entire proceedings not having been published, it is impossible to give here a complete notice of the meeting.

Dr. Swan M. Burnett, of Washington, D. C., reports a case of diplacusis binauralis. The phenomena described occurred in a patient aged 59. Dr. Burnett also reports a case of restricted range of audition.

The results of experiments with nitrate of amyl in tinnitus aurium are given by Dr. J. Michael, of Hamburg. He says the tinnitus in which the remedy is suggested is especially the hypertrophic form of middle ear disease, and in affections of the labyrinth. He was led to employ this remedy from its well-known sedative action upon the sympathetic system, especially the vaso-motor nerves, and the fact that many forms of tinnitus aurium are caused, not by an increased intra-labyrinthine pressure (Politzer, Weber), but occur as the result of nervous irritation of the auditory nerve, or of hyperæmia, or anæmia of the brain or the internal ear—the tinnitus resulting from the administration of quinine, salicylic acid, and other drugs, for example, being explained only in this manner. The remedy was employed in twenty-seven cases by himself, and in six cases by Dr. Urbantschitsch. A greater or less improvement occurred in nineteen cases. Among these were three in which the tinnitus disappeared entirely from one ear, and in the other was somewhat diminished. In four cases, a by no means inconsiderable improvement in the hearing was observable.

Three cases passed from observation. In the majority of cases there was an otitis media hypertrophica; of the cases not improved, one, and of those improved, two were labyrinth disease. Of the cases improved, one also was a purulent inflammation accompanied by polypi.

From one to five drops of the remedy was inhaled at a sitting.

The inhalation was continued during the appearance of the usual symptoms, flushing of the face, injection of the blood-vessels of the eye, etc., and suspended on the occurrence of vertigo. In all the cases improved, the tinnitus was increased during the period of inhalation. As the flushing of the face disappeared, the tinnitus diminished, and became less than before the application; the duration of the improvement after an inhalation was very varied. At the time of writing—three months—the improvement had persisted in one case. The details of cases are given, but they would take up too much space for this report.

This remedy has recently been employed in twenty cases by Dr. Spencer, of St. Louis, who was careful to select those cases which presented the most favorable conditions for its administration in the absence of any mere mechanical cause upon which the entotic noise could rest, and he reports the result to have

been wholly negative beyond a mere temporary impression.

Prof. Moos, of Heidelberg, enjoyed an unusual opportunity to study the histological changes that occur in the Eustachian tube from chronic catarrh, in a patient aged 41, who had suffered from catarrh of the ear since his ninth year.

Prof. Moos had this patient under his own treatment for ten years. For a stenosis of the tubæ Eustachii in consequence of this catarrh, Professor Moos undertook to open and dilate the tubes by means of catgut bougies. In this he was quite successful.

The patient died later, of some pulmonary disease, at the age of 49, having in the meantime become worse than ever as to his hearing, etc.

In a lengthy account of the condition in which he found the two tubæ Eustachii in this case, he first draws attention to the relative size of the osseum pharyngeum tubæ in its normal condition. It is seldom the same on both sides of the same individual. In the adult the sagittal diameter varies from 4.5 to 6.5 millimetres; the transverse diameter, from 4 to 5 millimetres. The depth of the cone is 5 to 6.5 millimetres.

He emphasizes the fact that when the osseum pharyngeum tubæ are remarkably small in the adult, in the absence of other causes, we may feel tolerably sure of the existence of a long-continued catarrhal disease of the mucous membrane of the Eustachian tubes.

As to other changes, the folds in the mucous membrane upon the floor of the tubæ were notably absent.

The folds in the mucous membrane opposite the floor of the tube below the curving of the medial into the lateral cartilages were totally wanting on both sides.

The conclusion is drawn, therefore, that one of the results of chronic catarrh of the Eustachian tube is a smoothing out of the folds of mucous membrane.

This favors a more intimate contiguity of the opposite surfaces of the tube than in the normal condition. As is shown further on, the smoothing of the folds is the result of increased activity of the muscles by whose contraction the canal is opened—the abductor tubæ and the salpingo-pharyngeus muscles. The mucous membrane, in cases of chronic catarrh, is often partially or wholly absent; owing perhaps to the increased frailty of the epithelial cells, his specimens were of this kind.

The submucosa, transformed by catarrh, presents a hyperplasia of the connective tissue; the fibrin layer is thicker and broader than normal.

The muciparous glands are atrophied and absorbed. Professor Moos believes that the tube, which is closed during rest, is dilated partially through the immediate or remote influences of musc. abductor tubæ, partially by the action of the superior and middle constrictors of the pharynx, by means of the facia salpingo-pharyngea, which is in simultaneous action with the pharyngeal muscles. If this view is correct, it might reasonably be expected that a hyperplasia of the organs concerned in dilating a tube where there has been disease of its canal for a series of years, with continued and increasing obstruction to the dilatation, would occur. In fact, his surmises proved to be correct. The facia salpingo-pharyngea was thoroughly hypertrophied.

The hyperplasia was characterized by a very dense quality of the connective-tissue bundles, partly by a broad ligamentous expansion of certain tendinous prolongations. This was particularly noticeable in parts where the prolongations were inserted into the

cartilaginous island on one side, and the submucosa of the floor of the tube on the other. The hyperplasia of the perichondrium led to an increased development of the intercellular substance of the cartilage, and in some portions of the tube the bands of connective tissue had penetrated between muscular bundles of the musculus levator, and gave the appearance of insular isolation of these portions. Other strikingly similar changes were found, but sufficient has been here gleaned from the article to indicate the very interesting character of these researches as a whole.

Professor Moos concludes that this state of things is the result of long-continued catarrh and of the increased labor demanded of the muscles of the part. In view of the fact that, in the normal condition of these parts, muscular fibre is never found in this situation, we may suppose a new formation of muscular fibre, a true (muscular) hypertrophy, to have occurred, provided, always, that we do not chance to meet a very rare individual peculiarity in the exceptional insertion of the muscle—a thing which nobody has as yet noted.

The changes in the cartilage were not of sufficient importance to be entitled to notice here.

Dr. L. Brewer Hall reports two cases of aspergillus in the ear. After some comments upon this subject he arrives at the conclusion that aspergillus glaucus in the auditory canal is rare in this climate; that the aspergillus is not the cause of the disease, but in order of time is a secondary phenomenon. The simplest effective treatment is to keep the meatus free and dry.

Dr. Roosa has been at the pains to observe the disproportion between the power of hearing the tick of a watch and the human voice in thirty-six cases. No cases were recorded where the watch could not be heard at all, or where it could be heard on one side only. Dr. Roosa's article is of greater interest than his apologetic remark at the opening would indicate. He says: "I am aware of the comparatively slight importance of the subject, but I hope the few facts shown may, at least, turn the attention of some observers, so that a careful working up of the questions involved may finally accomplish something for otological science."

Dr. Roosa refers to the importance of our possessing a good test or standard for testing the function of the hearing organ. We have, however, as yet been unable to acquire a satisfactory means.

It is to be regretted that the entire article cannot be given here. One deduction from the article is, that those cases are the least amenable to treatment in which the watch is heard relatively better than the voice. The conclusion of the article is devoted to the subject of hearing better in the midst of a noise.

Dr. Blake, in a paper published in 1875 (*Archiv. Ophth. et Otolology*), reported a case of movable cicatrix of the membrana tympani. The character of the movements of the cicatrix, the conditions under which these movements occurred, and the results of the tests to which these conditions were subjected, proving conclusively varying degrees of intra-tympanic pressure during natural respiration and during phonation, which could be explained only by assuming a persistent potency of the Eustachian tube.

In the *Archives of Oph. and Otolology* for August, 1876, Dr. Blake presents a second case confirmatory of the one mentioned above.

A new work upon the ear, by Dr. S. Burnett, of Washington, has appeared during the past year. Its title is, "The Ear: Its Anatomy, Physiology, and Diseases."

It is divided into two parts, the first being devoted

to Anatomy and Physiology, the second to Diseases and Treatment.

The illustrations of the book are well selected and are not too profuse.

The author adopts the metric system of measurements in his descriptions, anatomical and otherwise.

Dr. Burnett's well-known reputation as a scientific student would lead us to expect a very full account of the latest researches in otology; and in perusing the pages of his book one is not disappointed. Every department is thoroughly worked up.

We have the benefit of his thorough sifting of the latest literature upon the subject, in addition to his own mature observations.

The first part deserves special mention for its lucidity and thoroughness. The chapter on "Instruments and Methods of Employment" is a complete statement of the subject. That on sound-hearing and tests of the latter is carefully written.

The author recommends the use of the nasal douche for irrigating the naso-pharynx in acute and chronic affections of the middle ear. He thinks if every precaution laid down by him is resorted to, the operation can always be conducted with safety to the patient.

As the book will soon be in the hands of all, it is needless now to dwell upon a subject upon which there is such a diversity of opinion.

It is carefully prepared throughout, and is a valuable addition to the few good books written by otologists of late years.

### THREE CASES OF SPINAL DISEASE IN CHILDREN,

TREATED BY SUSPENSION WITH PLASTER-OF-PARIS JACKET, AT ST. JOHN'S RIVERSIDE HOSPITAL, YONKERS, N. Y.

By FRANK S. GRANT, M.D.,

LATE VISITING SURGEON.

CASE I.—Maggie Cameron, aged 4 years, born in U. S., admitted April 4, 1877. A pale-skinned, blue-eyed little girl, with scrofulous scars upon her neck and body. Her mother states that when three years old the child had a fall, which was subsequently followed by "a lump on the back," and inability to go around as before.

On examination there was discovered an angular curvature of the spine, involving the last three or four dorsal vertebrae. Pressure over this prominence gave no pain. In standing, the child would support herself by leaning forward, the hands grasping the thighs. In this attitude she could walk about the room. She had a good appetite, slept well, and played all day.

I explained the apparatus of Dr. Sayre to some ladies interested in the hospital, and they entered into the project with laudable zeal, giving me the means to purchase pulleys, etc. In the meantime I visited Dr. Sayre, at his office, and by his kind invitation spent the morning watching him put up several cases. On April 6th I put my little patient in the swing and applied the jacket. When the plaster had set she was allowed to walk about the ward, which she did with perfect ease, walking erect and unsupported. She wore the jacket until May 6th, when a fresh one was applied. The deformity had decreased visibly, and the patient had gained flesh during the month.

She continued perfectly well until June 1st, when,

after playing all the morning in the sun, she complained to the nurse of feeling tired, and laid down on a settee, where she fell asleep. On being removed to the ward in the early part of the afternoon she was very peevish and fretful, and complained of pain in the head. On my visit next day I found her in bed, with flushed cheeks, closed eyelids, and very restless; the nurse said the patient had moaned all night. I removed the jacket, had the child washed and placed apart from the other children. Temp. at this time was 100°; pulse, 110.

June 3d.—No better; passed a restless night, moaning and tossing about in bed.

June 4th.—The same; will take but little food; ordered potass. bromid., gr. ij. every three hours; temp. 100°; pulse, 105.

The patient continued in this way, taking no nourishment, and died quietly June 10th, exhausted. No post-mortem was allowed. The symptoms in this case were undoubtedly those of meningitis, subacute in character, and progressing to a fatal end.

CASE II.—Mamie Burns, aged 4 years, born in U. S., admitted to hospital April 30, 1877. Mother says the child fell down-stairs when two years old, and injured its spine.

On inspection I found disease of the three last cervical and the two last lumbar vertebrae; the deformity in the former was well marked, in the latter to a less degree.

The child's head appeared as if set below the shoulders, and rolled helplessly from side to side, when unsupported. The attitude of the patient was characteristic. She sat in her mother's lap, propping up and steadying her head with both hands under the chin, the elbows resting on the thighs. Upon examination of the chest I found emphysema in both lungs, with loud, asthmatic breathing. The patient was poorly nourished, thinly clad, and very dirty.

May 1st.—Put patient up in jacket with "jury mast." When removing the child from the swing to the bed I was alarmed by seeing her turn blue in the face and gasp for breath, with both hands tearing at the throat. I quickly replaced her in the swing, when as quickly the dyspnoea disappeared and the child breathed easily. Feeling assured that the jacket was not applied too tightly, for the flat of my hand could pass between the chest-wall and the dressing, I tried again to place her in bed after quieting her fears. There was no recurrence of the dyspnoea. The head-gear was put on next day, and the patient went about perfectly happy.

On June 5th the mother took her child home, but promised to report at the end of one week.

I heard nothing from her until June 25th, when she came with the child to the dispensary.

The patient had fallen away greatly, and the loud wheezing (which had become modified after wearing the jacket a few days) had returned. Both apparatus and child were in a filthy state. The jacket was removed, the patient washed, and again placed in the children's ward. I found, on examining the condition of the lungs, feeble respiratory sounds, coarse mucous and subcrepitant râles. Prescribed oil-silk covering to chest and cod-liver oil.

July 1st.—Condition so much improved that I reapplied the jacket, which was followed as before by improvement in the respirations. She kept fairly well through the months of July and August, running about the ward every day, and eating and sleeping well.

On September 2d I noticed she did not seem so

bright, and her breathing had grown noisy again. I had her kept quiet for a day, when the breathing became more natural. On September 5th her respiration again grew noisy, and I removed the jacket. There was no improvement of either spinal deformities.

Sept. 6th.—Seemed bright and happy, but with very feeble and wheezing respirations.

Sept. 7th.—At 11 A.M. she was seized with a paroxysm of choking; became rapidly cyanotic, and, after a few gasping respirations, fell back on the pillow dead. So sudden and unexpected was the attack that the nurse, who was in the next room, only reached her as she fell back on the pillow.

CASE III.—Lena Thompson, aged 7 years, born in U. S., admitted to hospital, 1877. When about four years of age she had her right leg amputated above the knee for disease in that joint. She was sent to the hospital, more for a home than for any apparent disease, but while treating the other spinal cases, my attention was called to this girl's spine.

I found angular curvature, with some lateral curvature involving the last dorsal and first lumbar vertebrae. In other respects she was in excellent health. She had worn at one time a form of spinal support, but without benefit, and it was cast aside. Shortly after her admission I placed her in the swing and applied the jacket.

The lateral curvature almost entirely disappeared while in the swing. She wore the jacket for one month with great comfort. I then put on a fresh one.

The nurse was instructed how to swing the patient every other day in the apparatus, from 15 to 20 minutes, my object being to gradually overcome the deformity—both lateral and angular—and follow it up with fresh jackets. Here, I regret to say, I shall be obliged to end the history of Case III., and for reasons which I shall give in my comments.

Comments.—The unfortunate ending of my first two cases has not discouraged me as regards this particular method of treatment, but has convinced me that it cannot be adapted to all cases indiscriminately.

Patient No. 1 certainly died of subacute meningitis, but not as a result of spinal irritation from the plaster-of-paris jacket, as had been inferred by some physicians. She had no unfavorable symptoms until after playing in the hot sun all the morning; she was a scrofulous child, and a poor case for test treatment.

Patient No. 2 died from a suffocative catarrh of the lungs, which may have been hastened by lack of sufficient chest expansion in consequence of the jacket, and yet the character of her respirations had improved a few days after its application.

Patient No. 3 was doing very well, and would have been a good case for test treatment had it not been interfered with. In the month of September, the governors of the hospital declared the treatment of spinal diseases by the method of suspension and plaster-of-paris jacket a failure, asserting that it had already killed two children, and forbidding its further use in the institution. To give emphasis to their opposition, the President of the Board came to the hospital, and by his own authority had the jacket removed from Case III., stating that he had come in time to save the child's life! In consequence of this act, I notified the hospital staff and retired from my service. This was immediately looked upon by the governors as a resignation of my office, and accepted as such.

YONKERS, N. Y.

## SOME METHODS OF APPLICATION TO THE UTERUS FOR CHRONIC DISEASE.\*

By FREDERICK D. LENTE, M.D.,

FORMERLY ONE OF THE PHYSICIANS OF THE N. Y. STATE WOMAN'S HOSPITAL.

SINCE the danger of making applications to the interior of the uterus by means of *injections* has been demonstrated, and therefore abandoned, the difficulty of efficiently treating the endometrium without previous dilatation of the cervical canal and os internum has been generally acknowledged by gynecologists, who have devised various contrivances of greater or less utility for this purpose.

The description of one of these instruments by Dr. Turner, of Brooklyn, in a recent number of THE MEDICAL RECORD, and his remark that he searched Tiemann's catalogue and the instrument stores in vain for an efficient instrument for making liquid applications, have led me to again direct the attention of the profession to an applicator devised by me some years ago, and which, according to the testimony of the manufacturers, has been quite extensively used. Dr. Turner's instrument only allows him to apply a very limited quantity of the liquid, or as much as will saturate a bit of cotton wrapped around a whalebone probe, which is then sheathed in a canula. Even this small quantity is more or less diluted with the secretion always present in the uterus, in case of disease, and fails to have the positive effect which we would have a right to expect from the potency of the agent employed. Moreover, such an instrument must necessarily be of considerable size, must, in many cases, require more or less force in its application, and give rise to some irritation of the sensitive parts. The principal objection, indeed, to most of the instruments designed for this purpose is their comparatively large size, and in the majority of them—not in Turner's, however—the want of any provision against the squeezing out of most of the fluid with which the cotton is saturated, as it passes through the canal, and the subsequent dilution and neutralization of what is left by the tenacious mucus which it there always encounters. To dilate the

canal previous to each application is to complicate the treatment, and in case it is effected by *tents*, to add very materially to the discomfort of the patient, and the expense, to say nothing of the occasional danger. The instrument which I described some years since is simply a small silver tube, resembling closely a male catheter, but with mere slits instead of eyes, to retard as much as possible the exit of the fluid; and furnished with an olivary enlargement an inch and a half from its extremity, to indicate when the latter has reached the os internum, in order that the operator may strictly

\* I find that the instrument-makers have manufactured my applicator of hard rubber instead of glass and silver, and have called it *Eutiles'* applicator; at least it goes under that name. The modification is certainly not an improvement, as some of the advantages, which I here claim, do not attach to it. For instance, its flexibility and small size, thus making dilatation or dragging down of the cervix (in order to straighten it) unnecessary; though hard rubber may also have its advantages. A few years ago an instrument maker used glass in place of hard rubber in making my *ointment syringe*, and called the instrument Hutchinson's, I think. I suppose, by way of making amends, they now substitute hard rubber for glass, thus "making things square."

F. D. L.

FIG. 1.

limit his application to the *canal*; or, on the other hand, to be certain that he has passed fully into the body of the uterus when this mark has disappeared in the canal. The calibre of the tube should be very small, and the walls sufficiently thick to obviate all danger of breaking from long use. The last three inches of the tube, including the bulb, should be of pure silver; the remainder must be of stiffer material or of larger size, in order not to bend too easily. To this tube is screwed an ordinary hypodermic syringe.

*Mode of Application.*—The liquid, first poured into a little cup or a teaspoon, is drawn into the syringe, and the latter screwed on the tube. It is then forced slowly into the latter until all bubbles of air have been expelled: the end is then wiped dry, and a very small quantity of the finest cotton-wool is twisted uniformly around the end beyond the bulb. (The advantage of not allowing any of the liquid to moisten the cotton is that the cervical canal is not irritated by it, and does not contract upon the instrument, thus rendering the operation more troublesome, and, in the case of a contracted and irritable canal, sometimes impossible). Having first passed into the uterus a probe terminated by an olivary bulb *somewhat larger* than the applicator with the cotton added, to insure that the os internum will *readily* admit the latter, and also to get the exact *direction* of the canal, the applicator is bent so as to correspond with this, and passed in. The cotton is then saturated by forcing out a few drops of the liquid, and wiped gently over the uterus, then a fresh supply is gradually added until it is seen to pass out of the external os by the side of the tube, as is readily done in the case of iodine, carbolic acid, etc. This, however, is not necessary, as we know that ten or twelve drops are sufficient for most cases. In withdrawing it is proper, when the *canal* is affected, to wipe the cotton thoroughly over all parts of it, and sometimes to supply fresh liquid from the syringe. In this way the most powerful drugs may be applied with the utmost precision, as we know, by previous trial, with a certain amount of cotton, just how many drops will saturate it, and we can thus limit the application strictly to the body of the uterus, in case the canal is unaffected, or the application unsuitable for it.

Messrs. Tiemann & Co. have figured in their valuable catalogue my "ointment syringe" for introducing with precision various ointments into the uterus (which Dr. Thomas also describes in his work), and have added a long tube which may replace the ointment tube, and the instrument may thus be used for both liquids and ointments, if the avoidance of *expense* is an object; but it is more convenient to have the two instruments, as the addition of the long tube to the ointment syringe makes it rather awkward. Their modification of the syringe to adapt it to liquids, since they have had to increase the length and diminish the diameter of the barrel, renders it less convenient for *ointments* than my original design, as it is necessary, in order to charge it, to have a very soft, almost semi-fluid ointment. Vaseline will be found probably the best excipient for any desired application, and may be rendered semi-fluid, if necessary, in cold weather. Calomel, oxide of zinc, etc., are very useful in this manner. Dr. Fordyce Barker has successfully used these applications, as he informed me, and had contrived an instrument previous to mine, but of an entirely different construction.

The effect of these applications, even in the most chronic cases, when made in this precise manner, is sometimes very striking, and the duration of treatment much shorter than when used with the ordinary applicators. No method, however, is so prompt and

effectual as the application of the solid *nitrate of silver* by means of the instrument which will be found described in Dr. Thomas's work, and which is here represented by Fig. 2. The effect on the prominent symptoms of some severe forms of chronic disease is

FIG. 2.

FIG. 3.

frequently astonishing. Among the poorer classes it is particularly applicable, since the treatment is thereby much curtailed and the expense lessened. But there is a drawback to this method in its liability to induce induration of the tissues, particularly of the cervical canal, if not judiciously used or if too long continued. But this is a minor evil compared to the miserable life, mental as well as physical, which the subjects of some of these forms of chronic disease endure, and which other milder applications fail to influence at all, or only for a brief period, and after a duration of months or years, if the patient does not get tired out and disheartened before the lapse of that time. As a general rule, however, in such cases, the application may be confined to the corporeal endometrium, to which this objection does not so strongly apply. The *pain* following the application of the nitrate, which should always be wiped thoroughly over the whole lining membrane, is such as to arouse fears of grave inflammation in the minds of those who are not familiar with its use. But this, when it occurs, can be almost immediately arrested by a hypodermic injection of morphia, or less promptly, but no less efficiently, by rectal injections of McMunn's elixir, when the stomach rebels against the morphia. I am not aware that any serious effects have ever occurred from its use, nor is it necessary to confine the patient to the recumbent posture longer than a few hours, while some of the poorer patients have gone about their

business at once, from necessity, without any injury. The symptoms scarcely ever produce any rise in the pulse or temperature. It may be well to state that the manner of charging the probe is to melt the nitrate in the platinum cup (a small, thin porcelain one will answer, but wastes the nitrate), then, after having well cleaned the bulb of the probe, to dip it in and out of the nitrate until a sufficient coating for the application has adhered to it. It then clings so closely that a blow from a hard instrument is required to detach it. This method of applying the nitrate is not applicable merely to the uterus; it may be and has been used for granulations, etc., at the bottom of the *meatus auditorius*, for sinuses, for the nasal cavity, the rectum, etc. The ointment syringe may also be used to great advantage in making applications to the nasal cavities, to sinuses, and to the prostatic portion of the urethra, instead of Lallemand's instrument, by means of a urethral tube which accompanies the syringe.

The liquid applicator is here represented by Fig. 1; the porte-caustique, with the platinum cup, by Fig. 2, and the ointment syringe by Fig. 3.

PALATKA, FLORIDA, November 1, 1877.

## Progress of Medical Science.

**DIFFERENTIAL INDICATIONS FOR THE USE OF THE FARADIC AND GALVANIC CURRENTS.**—In a pamphlet reprinted from the *New York Medical Journal*, Dr. A. D. Rockwell discusses the indications which are to guide us in the use of these two electrical currents. He considers his subject under three heads: 1st, those diseases, or symptoms of diseases, which seem to demand the faradic current; 2d, those that call for the galvanic; and 3d, those in which both are frequently and interchangeably indicated. Asthenopia, a symptom depending on an absolute or relative deficiency of energy in the muscles of accommodation, or of the internal recti, and accompanied by hyperaesthesia of the retina and of the ciliary nerves, is about the only disease in which faradization is invariably superior to galvanization. The galvanic current is uniformly superior to the faradic in spinal irritation, certain sequelae of cerebro-spinal meningitis, and in most of the skin affections in which electricity has been found of service. Of the third class, paralysis is the most prominent example. An exalted, or even a very slightly diminished electro-muscular contractility demands faradization; but a great diminution of this contractility indicates galvanization. Of the *modus operandi*, he accepts the explanation offered by Onimus, who claimed the duration of the current to be the important factor in the production of muscular contractions. The closing of the faradic current is only 0.0114" in duration, while that of the galvanic is 0.05"; hence, where the reaction of the diseased muscles is slow, the slower current is indicated. When used for the relief of pain, proper discrimination is difficult. True neuralgia is most successfully treated by galvanism, while hysterical neuralgia yields more readily to faradism. General faradization is highly recommended as a constitutional tonic.

**EXTRA-UTERINE PREGNANCY; GASTROTOMY.**—M. Rousseau, of Epernay, reports a case of extra-uterine pregnancy, in which gastrotomy was performed five months after the death of the fetus, and fourteen months after the commencement of the pregnancy. In order to produce adhesions and prevent opening into the peritoneal cavity, the actual cautery was used.

A knife-shaped instrument was heated to a white heat, and with it the anterior wall of the abdomen and the placenta, which was attached to it, were gradually divided; six sittings, at intervals of five or six days, were required for this purpose. After the sixth sitting the patient's condition was such as to render longer delay inadvisable, and the remaining portion of the placenta, which was about two-fifths of an inch thick, was divided with a bistoury. A little black blood escaped when the placenta was cut. The head could now be felt, and as it seemed large, craniotomy was performed and the bones of the cranium removed piecemeal. The entire fetus was then taken away without difficulty. Without the brain, and after being two days in alcohol, it weighed over six and a half pounds. The placenta was firmly attached to the abdominal wall, and bled on puncture. For fear of hemorrhage and of peritonitis, no attempt was made to remove it or the membranes. The patient did well immediately after the operation, but a few days afterwards was seized with a phlebitis, from which, however, she recovered speedily. There was no peritonitis at any time. The placenta did not slough out, but gradually diminished in size, and became involved in the cicatrix. Ten weeks after the operation the patient left the hospital, with a fistulous opening in the abdomen, from which a small quantity of thick pus escaped. This opening remained for several years, and during this period a tumor formed by the placenta and membranes could be felt in the abdomen. M. Rousseau claims that this case proves that the placenta and membranes can be left without fear in the abdominal cavity after gastrotomy, provided they are still living and attached. He thinks that the adoption of this practice as a rule will diminish greatly the unfavorable chances of the operation. In this case the cauterizations were not, as it turned out, necessary to prevent opening into the abdominal cavity, since the attachment of the placenta to the anterior wall of the abdomen removed all danger of that. They proved very useful, however, in preventing hemorrhage from the living and vascular placenta.—*Union Méd. et Scient. du Nord-Est.*, Sept. 30, 1877.

**INTRA-VEINUS INJECTIONS OF AMMONIA IN A CASE OF COLAPSE.**—Mr. Fitzgerald, of Melbourne, reports a case in which he employed intra-venous injections of ammonia with success, at a time when death was imminent from collapse. The patient had suffered for a long time from profuse suppuration. When first seen by Mr. Fitzgerald he was almost dead; he had no pulse at the wrist, and his respiration was imperceptible. Thirty drops of a solution of equal parts of *liquor ammoniæ fortior* and water were at once injected into a vein. The injection was followed by violent convulsions, but these soon passed off, and the patient was able to sit up in bed and talk rationally. These good effects persisted for eight hours, but the signs of collapse then reappeared. A second injection was practised, but the greater quantity of it passed into the cellular tissue, and no marked effect was produced. A third injection was more successful. The convulsive movements were more violent than after the first operation, but the effects were more satisfactory, for the alarming symptoms did not again return. The patient subsequently recovered completely. The ammonia that escaped into the cellular tissue produced a large eschar. With a little care this unpleasant result might have been avoided. It is thought that the intra-venous injections of ammonia deserve to be tried in other cases of collapse, and especially in cases of impending death from chloroform poisoning.—*Journal de Méd.*, etc., August, 1877.

# THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, December 29, 1877.

## THE LYING-IN HOSPITAL AT WASHINGTON.

IF the criticism on the management of the Columbia Hospital at Washington, by a citizen of that city, reprinted in pamphlet form from the Louisville *Medical Journal*, is correct in its material allegations, it is just possible that political hospitals are as corrupt as other political combinations proverbially are. The Woman's Hospital Association of Washington was incorporated by special act of Congress in June, 1866, on the ground, if our recollection rightly serves us, that it was highly improper that the capital of a great nation should not have a lying-in asylum of its own. Possibly that ground was not urged in exact terms, but merely intimated as one of the ulterior benefits of such an institution; for lobbyists as well as politicians are proverbially inexact in stating their real reasons for things. The project was, it appears, the happy conception of one Dr. J. Harry Thompson, who engineered the bill through Congress, and until September last was the surgical factotum of the institution, at a liberal salary and with a flexible board of directors, one of whom was General Orville E. Babcock. Until the fall of 1875, the doctor, now in Europe for his health, was in control of the funds of the institution as well as of its surgical instruments; and now arises the rather impertinent inquiry as to the administration of the \$227,000 appropriated to the hospital by the government during the last ten years.

The writer of the pamphlet in question brings to bear certain important allegations respecting the internal administration of the hospital, which can only be explained to a committee by the managing surgeon, such as that, although the institution was founded for the treatment of diseases peculiar to women, paying cases of consumption, malarial, typhoid, and remittent fevers have been admitted to its wards, to

the subversion of its proper function and of the proper hygienic conditions of a lying-in asylum. Again, although legally defined as an asylum in which those unable to pay therefor should be furnished gratuitously with board, lodgings, and medicine, and although the appropriations for that purpose have been large, the inmates have consisted mainly of patients paying from six to ten dollars a week for such benevolence. During the year 1875, for instance, Congress appropriated \$32,500, exclusive of the receipts from pay patients, making in all an amount of more than \$35,000 under the control of Dr. J. Harry Thompson. To descend to the dull detail of figures, the hospital managers throughout the country have the statistical fact that it takes \$1,187 (a little over three dollars a day) to support a patient for one year in a lying-in asylum, whereas one dollar per day is the average cost per patient to the government in the army hospitals of the United States. It is, perhaps, a little impertinent to ask the question; but, if sex makes such an extraordinary difference in the cost of maintaining a patient, the fact should be revealed to the medical world as one of the most important recent inductions of science. The medical profession in Washington, unable to appreciate the difference in sex at its proper value, caused a bill to be introduced in 1875, that limited the expenditure per patient to one dollar a day; and, as it became whispered about that his management was extravagant, the Board of Directors was compelled by pressure of public opinion to curtail Dr. Thompson's discretion a little, although he was still retained at his former salary. They accordingly elected an advisory and consulting board of physicians and surgeons from the medical men of the city, consisting of eight members, who, as counsellors, were required to visit the hospital once a week, and to report in writing the condition of the patients and of the building. But this board, unfortunately for the interests of the combination, reported too freely altogether, even carrying criticism so far as to submit certain recommendations of reform in writing to the Board of Directors, one of which was the appointment, after a competitive examination by a medical board, of a resident physician. Another sensible and important suggestion was to abolish the office of surgeon, and transfer his duties to a medical staff. To this eminently proper recommendation, the directors ludicrously rejoined that the purpose of the hospital was to treat special diseases and accidents, calling for special training and skill, and that it would, therefore, in their opinion, prove disastrous to its best interests to adopt the views of the advisory board. The absurdity of this decision (necessary to retain Dr. Thompson in office) can only be appreciated by calling to mind that that which the advisory staff recommended was really the adoption of a system that experience has everywhere justified, and one which is in successful operation in the

hospitals throughout the country, namely—the transfer of the medical management of the patients to a corps of physicians and surgeons, in lieu of entrusting them to a single person, however competent. Of course, the Board of Advisory and Consulting Physicians and Surgeons, having been thus pointedly snubbed, resigned *en masse*.

It is to be hoped, however, that the matter will not end here. No one acquainted with the history of the hospital, from its first foundation until the present, can doubt the fact that the institution has been managed in the interest of one man. That such should be the case in the capital of the country supplied by medical men of first-class talent, who would be willing to give services which were really valuable, for nothing, is almost past belief. The continued existence of the present board of directors is an insult to the profession of the country. It is time that this political ring was broken, and the hospital placed in the hands of those who can manage it properly and give it the best possible chance for real usefulness, not only to the public but to the profession.

#### HOW TO REMEDY DEFECTIVE VENTILATION IN SCHOOLS.

IN a recent examination concerning the ventilation of our public schools the President of the School Board is represented as saying that if the doctors and sanitarians would attend to the condition of the tenement-houses they would be better employed than in looking after the health of the school children. The inference would seem to be that if the Health Board could sufficiently improve the health of the children in the tenement-houses they could better endure the unsanitary condition of the school-rooms. Possibly if the children were never born, there would be no need of any ventilation whatever. As far as the argument goes it may be sound, but to unthinking and unpracticable individuals it may seem slightly evasive. While it is an evidence of some progress for him to acknowledge that the schools are not ventilated as they should be, it is also an evidence of his ability to deal with the problem by the way in which he approaches it. It is to be hoped that the medical profession will be impressed with the great importance of this advice, coming as it does from such high authority. The only thing now necessary to know is, what must be done with those children who do not live in tenement-houses and who attend the schools. The answer apparently suggests itself.

#### FRAUDS IN LIFE INSURANCE.

THE conviction of two presidents of life insurance companies for perjury is a promising offset to the recent reports concerning frauds in life insurance companies. Whenever any attempts have been made to examine the affairs of life insurance companies, the public have been made to believe that it was merely for the purpose of levying black mail, of

interfering with individual interests and hindering legitimate enterprise. For such apparent reasons the life insurance men have been always more or less active in opposing every legislative measure that, to ordinary people, might appear to be fair play to the insured. The developments in the recent trial throw a very strong light on such intentions, as the one who has been found guilty of the grossest kind of mismanagement was the person who was most active in preventing investigations.

#### BABY SHOWS AND CONTAGIOUS DISEASES.

THE report reaches us that one of the little ones who received the prize at the recent baby show has died of scarlet fever. Under ordinary circumstances the mere fact of a death from such a disease in a child of the age of the one in question is not extraordinary, but as one of the episodes of the recent baby show it has a certain significance. Whether the child took the disease at the show or not we are not prepared to say, but the probabilities are as much in that direction as in any other. Certain it is that the chances are increased in proportion to the number of children who were assembled together. How many other deaths from scarlet fever, or any other contagious disease, may occur in the other babies present on that occasion we shall, perhaps, never know, as the only reason why the information was furnished concerning this one was the necessity of completing the history of one of the prizes. If, as we hope, the case in question may be an isolated one, it is more a matter of good fortune than of deserved immunity. As baby shows are getting in the fashion, the attention of parents who believe they have prize children should be directed to the danger of such exhibitions. Not only may contagious diseases be propagated by the show babies, but by the outsiders who come to see them, to handle them, and, worst of all, to kiss them. Who can tell how many of these admiring spectators have come fresh from cases of measles, scarlet fever, or diphtheria, or how many children just convalescent from such diseases may be brought there by their nurses, because the latter wish to enjoy the apparent novelty of the occasion? But notwithstanding all this, we have no doubt that the baby shows will be popular all over the country.

#### THE ANTHROPOLOGICAL COLLECTION AT THE PARIS EXPOSITION.

IN the coming International Exposition at Paris there will be a section devoted to the study of the anthropological sciences. The opportunity for the collection of all matters bearing upon the present and prehistoric man will in all probability be unequalled. The gentlemen who will have charge of this department are anxious to secure the aid of ethnologists from all sections, but have extended a special invitation to gentlemen in this country who are interested

in the subject. It is by the grouping together of specimens from different portions of the globe that the missing links which now exist in our history of man can possibly be supplied. At all events, a concerted action on the part of the large number of physicians in this country who have studied the subject more or less thoroughly, will doubtless aid in settling many disputed points. America has been very fruitful in anthropological specimens, and scores of physicians have distinguished themselves in their study and interpretation. There is no doubt that many will be able to send to Paris contributions which, filling up some of the gaps in the history of America, will equal in importance the discoveries of Boucher-de-Perthes, Lyell, De Mortellet, and other builders of the prehistoric ages.

Necessarily the contributions must extend over a wide range of subjects. Not only must crania and bones be furnished, but mummies in whole or in part, instruments and methods of teaching among the primitive inhabitants, relics, photographs, pictures, drawings, sculptures, medals of prehistoric or ethnographic monuments, geographic charts and tableaux, books, periodicals and pamphlets concerning the ethnology, language, traditions, medical geography, etc., of the ancient and modern Americans.

The section will be under the charge of De Quatrefage, President of the Anthropological Society of Paris, Dr. Paul Broca, Vice-President, and many others. The importance of a hearty co-operation in the enterprise must be evident to all interested, and we accordingly invite such to place themselves in early communication with the American Educational Commissioner who shall be appointed to represent this and kindred departments at the Exposition.

#### THE CLOSE OF VOLUME XII.

WITH the close of the present volume we are reminded that some expression of thanks is due to our contributors and the members of our staff for the valuable aid which they have given us during the past year. Our contributors are duly mentioned by name in another place, and will accept collectively our obligations. Dr. Wesley M. Carpenter has, as usual, given us invaluable assistance by his admirable and accurate reports of lectures and transactions of societies. In these departments, also, we wish to acknowledge the good services of Drs. B. Brynberg Porter, of this city, Dr. S. M. Miller, of Philadelphia, and Dr. Norman Bridge, of Chicago. Drs. J. A. and Geo. P. McCreery, of this city, have translated and abstracted the items of progress of medical science from our German and French exchanges, and Dr. George R. Cutter, also of this city, has made the translations from our Scandinavian, Italian, Spanish, Holland, Russian, and Portuguese exchanges.

With the coming volume we shall endeavor, with the increased space at our command, to make such

improvements in the journal as increased experience in its management may suggest, and a more extended knowledge of the wishes of its patrons may demand.

#### ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from Dec. 16 to Dec. 22, 1877.*

BAILY, J. C., Major and Surgeon. Assigned to duty at the Presidio of San Francisco, as Post Surgeon. S. O. 158, Div. of the Pacific and Dept. of California, Dec. 12, 1877.

BACHE, D., Major and Surgeon. Assigned to duty at the Benicia Arsenal, and as Attending Surgeon at Benicia Barracks, Cal. S. O. 158, C. S., Div. of the Pacific and Dept. of Cal.

STORROW, S. A., Major and Surgeon. Relieved from duty at the Presidio, and to comply with orders from Headqrs. of the Army. S. O. 158, C. S., Div. Pacific and Dept. of Cal.

HARTSUFF, A., Major and Surgeon. Assigned to temporary duty at Fort Gratiot, Mich. S. O. 18, Dept. of the East, Dec. 13, 1877.

WOODHULL, A. A., Major and Surgeon. Until further orders, in addition to his present duties, to attend the sick at Angel Island, Cal. S. O. 158, C. S., Div. Pacific, Dept. of Cal.

WATERS, W. E., Capt. and Asst. Surgeon. To proceed to Fort Columbus, N. Y. II., settle his public business there, and, on completion thereof, report by letter to the Surgeon-General. S. O. 255, A. G. O., Dec. 15, 1877.

BROOKE, JNO., Capt. and Asst. Surgeon. Assigned to duty as Post Surgeon at Newport Barracks, Ky. S. O. 199, Dept. of the South, Dec. 14, 1877.

PHILLIPS, H. J., Capt. and Asst. Surgeon. Relieved from duty in Dept. of the East, and granted leave of absence for three months on Surgeon's certificate of disability, to take effect Jan. 1, 1878. S. O., 257, A. G. O., Dec. 18, 1877.

DE GRAW, C. S., Capt. and Asst. Surgeon. His resignation accepted by the President, to take effect Jan. 1, 1878. S. O. 257, A. G. O., Dec. 18, 1877.

LECTURES ON LIFE INSURANCE.—Prof. William Detmold, M.D., will give his course on Medical Examinations in Life Insurance, at the College of Physicians and Surgeons, every Friday (during the college term) at 2 P.M., commencing January 4, 1878.

# INDEX.

## A.

ABDOMINAL LESION; unique, 69, 143; pregnancy, 800.  
 Abortion, treatment of, 817.  
 Abscesses, treatment of, 70.  
 Abuse of medical charity, 217, 750.  
 Acetabulum, perforating fracture of, 93.  
 Acne, treatment of, 246.  
 Actual cautery for uterine fibroid, 42.  
 Adams, Dr. J. C., perityphlitis, 181.  
 Advertising portraits, 506.  
 After-pains, prevention of, 47.  
 Agaric bulbeux, 807.  
 Agnew, Dr. C. E., near-sightedness in school children, 34.  
 Agoraphobia, peculiar case of, 583.  
 Aiken, S. C., as health station, 781.  
 Albany ethics, 652.  
 Albany Medical College affairs, 32, 48.  
 Albuminuria, arsenic in, 520.  
 Alcohol, use and abuse in disease, 391.  
 Althof, Dr. Hermann, death of, 48, 223.  
 Alt, Dr. Adolph, the purple of the retina, 484.  
 Amaurosis, diagnosis of, 484.  
 Amblyopia, cases of, 99.  
 Ambrose Paré and the ligature, 303.  
 American Gynecological Society, 425; notice of, 299.  
 American Medical Association, meeting of the, 346, 369, 371; sections of, 386; notice of transactions of, 204.  
*American Bi-Weekly*, notice of, 48.  
 American diplomas abroad, 489.  
 American Neurological Association, 456.  
 American Dermatological Society, 616.  
 Ammonium chloride, inhalation of, 798.  
 Amputation, point of election in, 352; Esmarch's bandage in, 480.  
 Anæmia, remarks on, 87, 214; pernicious diseases of the medulla of bones in, 5.  
 Anæsthesia, a new discoverer for, 321; hysterical, 231.  
 Aneurismal tumors, case of, 92.  
 Aneurism, aconite and rest in, 169; of earotid cured by electricity, 586; cure of, by complete temporary pressure, 168; popliteal, cases of, 60, 478; thoracic, treated by electricity, 600.  
 Anderson, Dr. W. F., ovariectomy by the antiseptic process, 356.  
 Andrew, Dr. Geo. L., applications to Eustachian tube, 556.  
 Angular rotary curvature of spine—a question of priority, 363.  
 Ankle, excision of bones of, 27; sprains of, 21.  
 Anterior cornua, disease of, 505.  
 Anteflexion, treatment of, 408.  
 Anthropological collection at the Paris Exposition, 831.  
 Anuria lasting twenty-five days, 745.  
 Antiseptic method, the, 23; in midwifery, 370; in ovariectomy, 14, 74; in puerperal fever, 164.  
 Antiseptic surgery, notice of work on, 123.  
 Aorta, malposition of, 811.  
 Aortic lesions, treatment of, 595.  
 Aortitis, case of acute, 256.

Aphasia, syphilitic, 632; without lesions, 136.  
 Apomorphia, death following injection of, 664.  
 Appendix vermiformis, perforation of, 43.  
 Arkansas, State Medical Society of, 336.  
 Army news, 30, 62, 91, 95, 159, 208, 271, 335, 367, 383, 397, 464, 480, 575, 591, 607, 623, 671, 702, 718, 735, 752, 767, 782, 799, 814, 832.  
 Art in hospitals, 768.  
 Artery, obturator, surgical anatomy of, 630.  
 Arteries, calcareous degeneration of, 601.  
 Arthritis deformans in children, 796; suppurative, following acute rhenmatism, 531.  
 Ascites, cured by copaiba resin, 600.  
 Asphyxia from coal-gas, 528.  
 Asthma, remedy for, 261, 289.  
 Astragalus, excision of, 446.  
 Asylum abuses, 73, 91.  
 Atlee, Dr. W. T., sarcoma of the ovaries, 431.  
 Atomizer, a new antiseptic, 31.  
 Auscultation, a new method for, 33.  
 Autosite, a double, 24.

## B.

Baby shows and contagious diseases, 831.  
 Bacteria, 784; and eczema, influence of in bladder and urine, 86, 539; photographs of, 592; in water, 201.  
 Ball, Dr. A. B., Leube's meat solution, 175.  
 Balleray, Dr. G. H., hallux valgus, 532.  
 Bandage rolling machine, 511.  
 Barker, Dr. Fordyce, address by, 428; Tarnier's obstetric forceps, 683.  
 Bartholow, Dr. R., notice of work by, 10.  
 Bartlett, Dr. E., heat of fractures of clavicle, 541.  
 Bayles, Dr. Geo., nitrite of amyl in pertussis, 410.  
 Baynton, Dr. William N., revision of U. S. Pharmacopœia, 318.  
 Beard, Dr. Geo. M., electrolytic treatment of tumors, 161; endemic tetanus, 461; hay fever, 509; neurasthenia, 579.  
 Beardley, Dr. Chas. E., fracture dressing, 15.  
 Bed-sores, treatment of, 619.  
 Bed-bugs, remedy for, 431.  
 Belladonna, unilateral action of, 334, 397, 431.  
 Bellevue Medical College, Alumni, 672; commencement, 144.  
 Bellevue Hospital Reports, 19, 85, 167, 199, 245, 437, 487, 550, 597.  
 Bichloride of methylene, death from, 512.  
 Bile-ducts, rupture of, 638.  
 Biliary calculus in cystic duct, 361.  
 Billings, Dr. J. S., John Hopkins Hospital, 129, 145.  
 Billington, Dr., diphtheria, 140.  
 Birdsall, Dr. W. R., electro-therapeutics, 323.  
 Birth rate, period of maximum, 680.  
 Bladder, anal fistula of, 632; milk diet in disease of, 104; and rectum, cancer of, 362.  
 Blaps mortisagra as a human parasite, 299.  
 Blind, writing-machine for, 568.  
 Blockley Alms Hospital, Philadelphia, 246.

- Blood-corpuscles, signification of small red, 392, 505; structure of, 719; subcutaneous injection of defibrinated, 569; transfusion, death from, 398; white globules of, in certain maladies, 70.
- Bodenhamer, Dr. Wm., Are hemorrhoids salutary? 563.
- Body-snatching, 688.
- Bogus diplomas, 160, 682.
- Bones, how to stop bleeding from, 485; necrotic processes in, 70; percussion of the, 499.
- Bordeaux dressing for wounds, 614.
- Boston City Hospital, notice of reports of, 732.
- Boston Medical Charity, 767.
- Both, Dr. C., calcification in tuberculosis, 100, 451.
- Bowels, chronic inflammation of, 309.
- Boylston Medical Prize Questions, 512.
- Bradner, Dr. W. B., dislocation of patella, 46.
- Brain; base, lesion of, 769; circulation of, 291; remarkable duration of consciousness in concussion of, 20; experimental investigations on functions of, 135; localized lesions of, 296, 463; notice of work on functions of, 108.
- Braune's Atlas, review of, 250.
- Bravais' dialyzed iron, 235.
- Breakell, Dr. James A., spontaneous expulsion of foreign body from bronchial tube, 356.
- Briddon, Dr. Chas. K., aneurism by genu-flexion, 478; extirpation of rectum, 12, 235; perforation of appendix vermiformis, 43; Simon's exploration, 637.
- Bridge, Dr. Horatio, lumbo-colotomy, 154.
- Bright's disease; prevalence of, 784; treatment of, 199.
- British Medical Association, report of meeting of, 572, 624.
- Bromides, use and abuse of, 283.
- Bronchial casts, fibrinous, 205.
- Bronchitis, clinical lecture on, 513.
- Bronchocele, with metastatic deposits in lungs and bones, 119; case of, 205.
- Bronchus, spontaneous expulsion of foreign body from, 356; nutshell in for thirteen years, 488.
- Bronson, Dr. John R., address by, 392.
- Brown, Dr. J. W., retro-pharyngeal abscess in diphtheria, 78; tania by carbolic acid, 813.
- Brown-Séguard, Dr. C. E., nervous diseases, 764.
- Bubonocoele, case of, 133.
- Buck, Dr. A. H., danger of introducing fluids in nasal passages, 177; desquamative processes in the ear, 786.
- Buck, Dr. Gordon, review of work by, 7; death of, 158, 185, 192, 256, 272, 302.
- Budd, Dr. C. A., death of, 335, 702.
- Bulkley, Dr. H. D., eczema, 617.
- Bull, Dr. C. S., chorea and errors of refraction, 339; fracture of bones of the face, 546, 804; hysterical hemiplegia, 99.
- Bumstead, Dr. S. J., the homœopathic question, 555.
- Burrall, Dr. F. A., new atomizer, 542; chloroform poisoning, 123.
- Burnett, Dr. Swan M., nitrite of amyl in tinnitus aurium, 483.
- Burns, a cure for, 672.
- Byrd, Dr. W. A., new bandage rolling machine, 511.
- Byrne, Dr. J., excision of cervix uteri, 425.
- Cardiac dilatation, 362; disease, acute, complications of, 737.
- Caro, Dr. S., morphia, influence of, on children in utero, 766; successive miscarriages, 476.
- Carotid, aneurism of, cured by electricity, 586.
- Carpal bones, caries of, 41.
- Carpenter's physiology, notice of, 108.
- Carpus, exsection of, 477.
- Carroll, Dr. A. L., abortive treatment of pneumonia, 125.
- Caswell, Dr. Ed. T., ligation of external iliac artery, 613.
- Catgut ligature, uses of, 759.
- Catheter gauge, new, 638.
- Cell doctrine, the, 94; nucleus, structure of, 216.
- Cellar, unhealthy, 800.
- Centenarian, specimens from a, 326.
- Centennial Exposition, diseases of the, 76.
- Century of American Medicine, notice of work on, 9.
- Cerebellum, diagnosis of tumors of, 247.
- Cerebral artery, sacculated aneurism of, 526; localizations, 215, 791; thermometry, 778.
- Cerebro-spinal meningitis, 237.
- Cervix uteri, excisions of, 425; laceration of, 657; shortening of during utero-gestation, 644.
- Chamberlain, Dr. W. M., antiseptic treatment of puerperal fever, 164; gutta-percha, 623.
- Champagne, consumption of, 752.
- Chancre and epithelioma, 279.
- Chancroid, remarks on, 155.
- Charity, medical abuse of, 455.
- Chase, Dr. Walter B., puerperal fever and erysipelas, 30, 62.
- Cheap medical education, 171, 202, 207, 234, 238.
- Chemistry, notices of works on, 108, 443.
- Chicago, medical matters in, 331.
- Children, care of the, 359; notice of work on, 283.
- Cluness, Dr. W. R., edgewise dislocation of patella, 61.
- Chittenden, Dr. D. J., pressure in delayed labor, 510.
- Chloroform, dangers of, 345, 428; death from, 31, 40, 47, 48, 90, 251, 260, 399, 496, 559; and dentistry, 25, 31; narcosis, changes of pupils in, 535; poisoning, treatment of, 123, 576; and rape, 815; symptom of action of, 38.
- Cholera, notice of work on, 172.
- Chorea, embolic theory of, 103; errors of refraction, 339, 415; post-hemiplegic, 462; treatment of, 214, 215, 785.
- Churchill, Dr. J. H., new method of obtaining extension and counter-extension in fractures of the femur, 167.
- Cigar, perils of the, 423.
- Ciliary processes, changes of during accommodation, 37.
- Cincho-quinine, remarks on, 15, 46.
- Cinchonia and quinina, 357.
- Claiborne, Dr. J. H., quinine and urticaria, 814.
- Clarke, Dr. Almon, perityphlitic abscess, 612.
- Clarke, Dr. E. H., death of, 799.
- Clavicle, dislocation of, 22, 517, 541; treatment of fracture of, 20, 662.
- Cleborne, Dr. C. J., croton chloral in dentistry, 316; gonalgia, 533; tenaculum needle, 655.
- Cleft palate, operations for, 498.
- Clelland, Dr. John, notice of work by, 171.
- Clitoris, tumor of, 382.
- Club-foot, treatment of, and suit for malpractice, 495.
- Coccyx and sacrum, curious case of necrosis of, 439.
- Coleman, Dr. John S., nervous lesion of abdominal wall, 69; multiple wedge in the treatment of stricture, 174.
- Colica pictorum, 551.
- College affairs, etc., 112, 159, 160, 208, 240, 271, 587.
- Colles's fracture, new splint for, 391.
- Colon, carcinoma of, 41.
- Color line in medicine, 667, 810.
- Colorado, as a climate for consumption, 378.
- Colvin, Dr. D., croup and diphtheria, 191.
- Compressed air, new instrument for, 635.
- Connecticut State Medical Society, 347, 350; notice of transactions of, 668.

## C.

Cæsarean section, post-mortem, 752.

Calabar bean in tetanus, 567.

Calcification in tuberculosis, 100.

Calcium, chloride of, 791.

Calculeous concretion upon broom straw, case of, 19; calculous disease, notice of work on, 204.

Caldwell, Dr. John J., damiana, 694.

Caldwell, Dr. W. S., treatment of rheumatism, 556.

Camphor, saturated spirit of, poisoning by, 485.

Carbolated camphor as a surgical dressing, 134.

Carbonic oxide, how to detect it in a room, 559.

Connective tissue, plasmatic channels in, 104.  
 Consanguineous marriages, 389.  
 Constipation, remarks on, 167, 273, 405.  
 Contagious disease, spread of, 48, 442, 794.  
 Contract practice, remarks on, 590.  
 Convulsive disease without convulsion, 410.  
 Cook County Hospital reports, 470, 758.  
 Coroner, abolition of office of, 105.  
 Coroners, none in France, 368.  
 Copper, physiological position of, 404; earrings, unpleasant consequences of, 560.  
 Copperhead snake, cure of bite of, 543.  
 Corpus luteum, report on, 426.  
 Cough mixture, 488.  
 Cowling, Dr. R. O., method of measuring the lower extremities, 300.  
 Cows, milch, tuberculosis in, 389.  
 Crauial sarcoma, case of extensive, 525.  
 Cremation; in Switzerland, 784; rules for, 672.  
 Crescent and Cross Society, 768.  
 Cresotinic acid in acute articular rheumatism, 276.  
 Crime, microscope in the detection of, 588.  
 Criminal insane, care of, 80.  
 Crosby, Dr. A. B., death of, 527, 543, 591.  
 Croup, and diphtheria, 109, 125, 191; treatment of, 231, 246, 552, 695, 700.  
 Culbertson, Dr. H., notice of work by, 523.  
 Croton chloral, 232, 316.  
 Cyanosis, an obscure case of, 310, 337.

## D.

Dalton, Dr. J. C., report on corpus luteum, 426.  
 Damiana, fluid extract of, 694.  
 Deafness, left-sided, 544.  
 Death, state of eyelids in, 4; sudden, without apparent cause, 476, 636.  
 Delafield, Dr. F., diabetes insipidus, etc., 305; laryngeal diphtheria, 93; pulmonary emphysema, etc., 289.  
 Delivery, how long should women stay in bed after, 687.  
 Dental; neuralgia, excision of nerve for, 792; caries, cause of, 711.  
 Dermic medication, 432.  
 Dessau, Dr. S. H., small doses, 465.  
 Detmold, Dr. W., lectures on life insurance, 81, 97, 113.  
 Diabetes, constipation of, 274; excretion of creatinin in, 72; insipidus, 278, 305; mellitus in health, 550; treatment of, 523.  
 Dialyzed iron, popularity of, 567.  
 Diaphanoscopy in the examination of female pelvic organs, 247.  
 Diaphragmatic peritoneum, structure of, 650.  
 Diarrhoea, remarks on, 2, 232, 405.  
 Didama, Dr. H. D., late meeting of British Medical Association, 572.  
 Diphtheria, remarks on, 78, 93, 109, 120, 138, 275, 293, 391, 445, 602, 647, 695, 701.  
 Diplococcus hauralis, 693.  
 Diplomas, bogus, 160, 682.  
 Discipline, how to maintain, 666, 698.  
 Discussions, medical remarks on, 170.  
 Disinfectant, an efficient, 40.  
 Dispensary abuses, remarks on, 716.  
 Dissections, notice of work on, 171.  
 Dobell, Dr. H., review of work by, 91.  
 Doctors, scarcity of, in Russia, 747.  
 Drainage tubes, accidental loss of, in pleural cavity, and removal by operation, 150.  
 Druggists and physicians, relations of, 350; weights, 137, 186.  
 DuBois, Dr. H. A., movement in the treatment of fracture of the external condyle of humerus, 432; open treatments of wounds, 179; treatment of fractures of thigh, 481; vaseline, 244.  
 Dudley, Dr. D. E., new ophthalmoscope, 767.

Duellists, relation of surgeons to, 26.  
 Duhring, Dr. L. A., notice of work by, 251, 323.  
 Dunglison, Dr. R. J., notice of work by, 732.  
 Dupuy, Dr. E., on headache, 329; hereditary epilepsy, 459; reflex motor symptoms, 44.  
 Dysentery, treatment of, 181, 711.  
 Dysmenorrhoea, remarks on, 625, 675, 685, 701.  
 Dyspepsia, dilatation of stomach in, 472, 711.

## E.

Ear, desquamative diseases of, 786; douche for, 542; foreign body in middle, 602; report on diseases of, 820; syphilitic disease of internal, 631.  
 Earache, a new treatment for, 17.  
 Eczema, notice of work on treatment of, 10; remarks on, 96, 472, 617.  
 Ectropion, new treatment of, 54.  
 Edebohls, Dr. Geo. M., cresotinic acid in rheumatism, 276; treatment of rheumatism, 776.  
 Edel, Dr., canceroid tumors of perineum, 205.  
 Editorial puffing of advertisers, 264.  
 Edson, Dr. Benj., diphtheria, 275.  
 Education, medical, in France, 736; in Vermont, 395.  
 Egg, hen's, fecundation of, in oviducts, 552.  
 Elastic bandage and anaesthesia, 527.  
 Elbow, excision of, 55; excision of, 477.  
 Electric bath, notice of work on, 91.  
 Electrical treatment, injury from, 760.  
 Electrolytic treatment of tumors, 161, 172, 382.  
 Elephantiasis of leg, ligation of popliteal for, 440.  
 Ely, Dr. Edward T., on history of hypermetropia, 149.  
 Ely, Dr. Smith, perityphlitic abscess, 613.  
 Electro-therapeutics, cases in, 323.  
 Embalming, new process of, 720.  
 Embolism, sudden death from, 119.  
 Emphysema, remarks on, 289.  
 Empyema, remarks on, 206, 236, 325, 471, 477, 496, 550, 631.  
 Eucephalic circulation, 291.  
 Endocarditis blennorrhoeica, 505; ulcerative, 219.  
 Endowment of medical colleges, 152, 269, 287, 298.  
 Enteric fever, etiology of, 388.  
 Epididymitis, blennorrhagic, treated by iodoform ointment, 570.  
 Epilepsy, iron in, 696; prevention of, 248; tension of blood in, 779.  
 Epileptic attacks, treatment of, 423.  
 Epiphysis of humerus, fracture of, 760.  
 Ergotine, parenchymatous injection of, 624.  
 Erysipelas and puerperal fever, 391.  
 Erythroxyton coca, 253.  
 Erwin, Dr. R. W., submucous ligation of hemorrhoids, 805.  
 Esmarch's bandage, bad result from, 325.  
 Expert testimony, 508.  
 Extravasation, secondary hemorrhagic, 12.  
 Extremities, epidemic contraction of, 104.  
 External iliac artery, ligation of, 312, 352, 613.  
 Ether, dangers of, 496; death from, 398.  
 Eustachian tube, applications to the, 556.  
 Eve, Dr. Paul F., death of, 735.  
 Eye and Ear Infirmary, report of, 63.  
 Eyeball, case of ossification of, 536; serious contusion of, 804.  
 Eyelids, state of, in death, 4.  
 Eyes, care of the, 229; change of form under education, 732; drainage of, by catgut, 520; how to get rid of a blackened, 679.

## F.

Face, fracture of bones of, 546, 677.  
 Faculty, prize examination, 224.  
 Fairfield, F. G., bacteria in urine, 539; microscope in the detection of crime, 588.

- Families, size of, in Colombia, 688.  
 Famine in India, 592.  
 Febris recurrens in Poland, 816.  
 Feet, a remedy for excessive sweating of, 576.  
 Felton, Dr. A. D., Is typhoid fever contagious? 84.  
 Felton, Dr. L. E., apparatus for new inhaler for chloride of ammonium, 798.  
 Female, exstrophy of bladder of, 603; education, 672.  
 Femur, dislocation of, diagnosis of, 393; luxations of, from paralysis, 712; osteo-sarcoma of, 11; refracturing of, 19; treatment of fracture of, 753.  
 Fergusson, Sir William, death of, 112.  
 Ferrier, David, notice of work by, 108.  
 Fever, hemorrhagic, treatment of, 272; lectures on, 401, 763.  
 Fever cot, a new, 79.  
 Fibula, excision of portion of, for compound fracture of leg, 386.  
 Field, Dr. Chauncey M., needle in trachea, 148.  
 Field, Dr. Henry M., puerperal fever and erysipelas, 62.  
 Filaria hæmatica, 261.  
 Filiaris sanguinis hominis, 779.  
 Finnell, Dr. T. C., hemorrhagic extravasation in forearm, 12; tumor of neck, 670.  
 Fires in schools, prevention of, 64.  
 Fissure of the anus in infants, 296, 743.  
 Flexions, intra-uterine, treatment of, 429.
